The Foundations of Psychiatry

Table of Contents

CONTRIBUTORS

Ian Alger, M.D.

Visiting Associate Clinical Professor of Psychiatry, Albert Einstein College of Medicine, New York; Clinical Assistant Professor of Psychiatry and Training Psychoanalyst, New York Medical College, New York.

Heinz L. Ansbacher, Ph.D.

Professor Emeritus of Psychology, University of Vermont; Editor, Journal of Individual Psychology.

E. James Anthony, M.D.

Blanche F. Ittleson Professor of Child Psychiatry, and Director, Eliot Division of Child Psychiatry, Washington University School of Medicine, St. Louis.

Kenneth Appel, M.D.

Professor Emeritus, Department of Psychiatry, University of Pennsylvania, Philadelphia, Pennsylvania.

Silvano Arieti, M.D.

Clinical Professor of Psychiatry, New York Medical College, New York; Training Analyst and Supervisor, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York.

Jack Bemporad, M.D.

Rabhi, Temple Emanu-El, Dallas, Texas; Past Director of the Commission on

Worship of the Union of American Hebrew Congregations.

Jules R. Bemporad, M.D.

Director of Pediatric Psychiatry, Babies Hospital, Columbia-Presbyterian Medical Center, New York; Faculty Member, Psychoanalytic Division, New York Medical College, New York.

Therese Benedek, M.D.

Senior Staff Member, The Institute for Psychoanalysis, Chicago, Illinois.

Viola W. Bernard, M.D.

Former Clinical Professor of Psychiatry, Columbia University; Staff Psychoanalyst, Psychoanalytic Clinic for Training and Research, Columbia University, New York.

Donald A. Bloch, M.D.

Director, Nathan W. Ackerman Family Institute, New York; Editor, Family Process.

Henry Brill, M.D.

Director, Pilgrim State Hospital, West Brentwood, New York; Clinical Professor of Psychiatry, Down- State Medical Center, Stony Brook, New York.

Robert N. Butler, M.D.

Research Psychiatrist and Gerontologist, The Washington School of Psychiatry, Washington, D.C.; Associate Clinical Professor, Howard University

School of Medicine, Washington, D.C.

Nancy Datan, Ph.D.

Assistant Professor of Psychology, Department of Psychology, West Virginia University, Morgantown, West Virginia.

Katrina De Hirsch, F.C.S.T.

Former Lecturer in Pediatrics, College of Physicians and Surgeons, Columbia University; Director of Pediatric Language Disorder Clinic, Columbia Presbyterian Medical Center, New York.

Marvin G. Drellich, M.D.

Associate Clinical Professor of Psychiatry and Assistant Director of the Division of Psychoanalysis, New York Medical College, New York.

Abraham Edel, Ph.D.

Distinguished Professor of Philosophy, City University of New York Graduate School; Professor of Philosophy, The City College, New York.

Leon Edel, Ph.D.

Citizens' Professor of English, University of Hawaii; Member, Academy of Arts and Letters.

Henri F. Ellenberger, M.D.

Professor, Department of Criminology, University of Montreal; Psychiatrist, Hotel-Dieu Hospital, Montreal, Canada.

James L. Foy, M.D.

Associate Professor, Department of Psychiatry, Georgetown University School of Medicine, Washington, D.C.

Eugene A. Friedmann, Ph.D.

Professor of Sociology and Chairman, Department of Sociology and Anthropology, Kansas State University, Manhattan, Kansas.

Richard A. Gardner, M.D.

Assistant Clinical Professor of Child Psychiatry, Columbia University, College of Physicians and Surgeons, New York; Faculty Member, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York.

Kurt Goldstein, M.D.

Deceased.

Ralph R. Greenson, M.D.

Clinical Professor of Psychiatry, University of California, Los Angeles, School of Medicine; Chairman, Scientific Advisory Board, Foundation for Research in Psychoanalysis, Beverly Hills, California.

Harry Guntrip, Ph.D.

Fellow of the British Psychological Society; Psychotherapist and Lecturer, Department of Psychiatry, Leeds University, England.

Joseph L. Henderson

Assistant Clinical Professor of Neuro-Psychiatry, Stanford University Medical School, California; President of the C. G. Jung Institute of San Francisco.

John W. Higgins, M.D.

Late Associate Professor Clinical Psychiatry, St. Louis University, St. Louis, Missouri.

Irene M. Josselyn, M.D.

Training Analyst, Southern California Psychoanalytic Institute; Member of Child Analysis Committee, American Psychoanalytic Society.

Bernard Kaplan, Ph.D.

University Professor and Professor of Psychology, Clark University, Worcester, Massachusetts.

Kenneth Keniston, Ph.D.

Professor of Psychology (Psychiatry), Yale University School of Medicine; Chairman and Executive Director, Carnegie Council on Children, New Haven, Connecticut.

Nolan D. C. Lewis, M.D.

Former Head, Department of Psychiatry, College of Physicians and Surgeons, Columbia University, New York.

Theodore Lidz, M.D.

Professor of Psychiatry, Yale University School of Medicine, New Haven,

Connecticut; Career Investigator, National Institute of Mental Health.

Harold I. Lief, M.D.

Professor of Psychiatry and Director, Division of Family Study, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.

Bruce Mazlish, Ph.D.

Professor of History, Massachusetts Institute of Technology, Cambridge, Massachusetts.

Rev. James R. MacColl, III, D.D.

Former President, Academy of Religion and Mental Health; Chairman of Executive Committee, Institutes of Religion and Health.

R. E. Money-Kyrle, Ph.D.

Full Member, British Psychoanalytical Society.

George Mora, M.D.

Assistant Clinical Professor of Psychiatry, New York Medical College, New York; Research Associate, Department of History of Science and Medicine, Yale University, New Haven, Connecticut.

Wendell S. Muncie, M.D.

Associate Professor of Psychiatry, Johns Hopkins University, Baltimore; Consultant, Springfield State Hospital, Sykesville, Maryland.

Simon H. Nagler, M.D.

Clinical Professor of Psychiatry, Director of Psychiatric Residency Training, and Director of Psychoanalytic Division, Department of Psychiatry, New York Medical College, New York.

Bernice L. Neugarten, Ph.D.

Professor, Human Development, and Chairman, Committee on Human Development, University of Chicago, Chicago, Illinois.

Daniel Offer, M.D.

Associate Director, Institute for Psychosomatic and Psychiatric Research and Training, Michael Reese Hospital and Medical Center; Professor of Psychiatry, Pritzker School of Medicine, University of Chicago, Chicago, Illinois.

Harold L. Orbach, Ph.D.

Associate Professor of Sociology, Kansas State University, Manhattan, Kansas; President, Midwest Council for Social Research in Aging, Kansas City, Missouri.

E. Mansell Pattison, M.D.

Associate Professor and Vice-Chairman, Department of Psychiatry and Human Behavior, University of California at Irvine; Deputy Director, Training and Manpower Development Division, Orange County Department of Mental Health, Santa Ana, California.

Isidore Portnoy, M.D.

Associate Dean, American Institute for Psychoanalysis; Attending

Psychoanalyst, Karen Homey Clinic, New York.

John D. Rainer, M.D.

Professor of Clinical Psychiatry, College of Physicians and Surgeons, Columbia University; Chief of Psychiatric Research (Medical Genetics) New York State Psychiatric Institute, New York.

Anatol Rapoport, Ph.D.

Professor of Psychology and Mathematics, University of Toronto, Canada.

Paul Ricoeur

Professor of Philosophy, University of Chicago and University of Paris.

Alfred H. Rifkin, M.D.

Clinical Associate Professor of Psychiatry, New York University School of Medicine, New York; Associate Clinical Professor of Psychiatry, New York Medical College, New York.

Alan K. Rosenwald, Ph.D.

Chairman, Department of Psychology, Illinois State Psychiatric Institute, Chicago, Illinois.

Joseph F. Rychlak, Ph.D.

Professor of Psychology, Department of Psychological Sciences, Purdue University, West Lafayette, Indiana.

Melvin Sabshin, M.D.

Professor and Chairman, Department of Psychiatry, Abraham Lincoln School, University of Illinois, College of Medicine, Chicago, Illinois; Medical Director-designate, American Psychiatric Association.

David E. Schecter, M.D.

Director of Training, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York.

Edward C. Senay, M.D.

Director, Illinois Drug Abuse Programs; Associate Professor, Department of Psychiatry, University of Chicago, Chicago, Illinois.

Natalie Shainess, M.D.

Faculty Member, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York; Lecturer in Psychiatry, Columbia University, College of Physicians and Surgeons, New York.

William M. Sheppe, Jr., M.D.

Clinical Associate Professor, Department of Psychiatry, University of Virginia School of Medicine, Charlottesville, Virginia; Medical Director, Central Virginia Psychiatric Associates, Inc., Charlottesville, Virginia.

Cyril Sofer, Ph.D.

Fellow of Queens' College and University Reader in Industrial Management, Cambridge, England.

John A. Sours, M.D.

Private practice; Assistant Clinical Professor of Psychiatry, Columbia University, Psychoanalytic Clinic for Training and Research, New York.

Rose Spiegel, M.D.

Training Analyst and Supervisor, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York; Associate Psychiatrist, New York State Psychiatric Institute, New York.

Ian Stevenson, M.D.

Carlson Professor of Psychiatry, Department of Psychiatry, University of Virginia School of Medicine, Charlottesville, Virginia.

Alberta Szalita, M.D.

Clinical Professor of Psychiatry and Training and Supervising Analyst, College of Physicians and Surgeons, Columbia University, New York; Visiting Professor, Tel-Aviv University, Tel-Aviv, Israel.

Ludwig von Bertalanffy, Ph.D.

Late Faculty Professor, Natural and Social Sciences, State University of New York at Buffalo.

Eilhard Von Domarus

Late Fellow and Member of the Board of Directors, Association for the Advancement of Psychotherapy; Late Supervisor, Postgraduate Center for Psychotherapy, New York.

Joseph B. Wheelwright, M.D.

Professor of Psychiatry, Langley Porter Clinic, San Francisco, California; Past President of the International Association of Analytical Psychology.

Earl Witenberg, M.D.

Director, William Alanson White Institute of Psychiatry, Psychoanalysis and Psychology, New York.

Milton Wittman, D.S.W.

Chief, Social Work Training Branch, Division of Manpower and Training Programs, National Institute of Mental Health, Alcohol, Drug Abuse, and Mental Health Administration, Department of Health, Education and Welfare, Rockville, Maryland.

Joseph Wolpe, M.D.

Professor of Psychiatry, and Director of the Behavior Therapy Unit, Temple University Medical Center and Eastern Pennsylvania Psychiatric Institute, Philadelphia, Pennsylvania.

PREFACE

Among the disciplines which are growing at the most accelerated pace is psychiatry, and understandably so. Intimately involved with general biology, neurology, psychology, sociology, cultural changes of any kind, it is constantly enriched by these fields and many others, which all converge toward a greater knowledge of man in health and mental illness.

When one looks at the first edition of this Handbook several thoughts emerge: how much of its content has preserved its validity; how little is no longer acceptable; but, most of all, how much is missing from it which we are now in a position to include. And yet the initial two volumes of the first edition appeared in 1959; the third in 1966. The time elapsed is short, but the work done in the field in these intervening years is enormous. A new and larger edition has thus become necessary. The success of the first edition, not only in the United States but throughout the world, gave the inspiration and provided the energy necessary for the preparation of this second edition.

When this new edition was planned it soon became evident that I could no longer be the only editor, as I had been for the 1959-1966 edition. It is increasingly difficult for one person to have the necessary competence in the many areas of rapidly expanding psychiatry. The need for section editors became a necessity. I am responsible for the planning, general organization,

and division of the work; but competent colleagues have joined me in editing the various volumes. Only Volume One, "The Foundations of Psychiatry," is edited by me exclusively. Dr. Gerald Caplan is the editor of Volume Two, which deals with "Child and Adolescent Psychiatry, Sociocultural and Community Psychiatry." Volume Three, devoted to "Adult Clinical Psychiatry," is edited by Dr. Eugene B. Brody and myself. Volume Four, dealing with "Organic Disorders and Psychosomatic Medicine," is edited by Dr. Morton F. Reiser. Drs. Daniel X. Freedman and Jarl E. Dyrud have edited Volume Five, dealing with "Treatment," and Drs. David A. Hamburg and Keith Brodie have edited Volume Six, "New Psychiatric Frontiers."

The basic philosophy and guidelines of the first edition will be recognized in the second. All orientations, all schools, all respectable methods of treatment are represented in these volumes. Some of these approaches converge and integrate, others diverge. They actually represent in the field of psychiatry the spirit of innovation and the state of flux of modern man. At the present stage of our knowledge any attempt to integrate some approaches and to exclude others would not lead to higher syntheses or to a consistent view of psychiatry or of man, but to one or another brand of reductionism.

Completeness was preferred to simplification, representation of contrasting views and reliability were preferred to uniformity and attempts toward consistency. Each author was requested to cover his special field; he

was free to express his personal point of view, but he was asked in almost all instances to present alternative conceptions and to reduce his private terminology to a minimum or to define it immediately. The chapters of these volumes differ from those of usual textbooks in being more complete, more analytical, and more authoritative without reaching monographic proportions. Except for Volume Six, no attempt was made to put emphasis on new or fashionable developments. Currently accepted or classical concepts are presented together with new findings and innovating ideas.

The authors who were invited to participate in this project are in most instances recognized authorities in their respective fields. In several instances, the task of selecting the author was difficult because many people had made important contributions in the same field. The search for recognized authorities did not lead us to discriminate against young age. Several chapters are written by promising young authors. Some colleagues whom we would have liked to have join us, could not participate because of heavy involvement in other work.

Repeating some of the words of the preface to the first edition, I wish to say that this book is offered as representative of American psychiatry today. "American," used in this context, refers specifically to the receptivity to all possible approaches which is characteristic of psychiatry in the United States. Although most of the great psychiatric contributions originated in Europe, in

no country other than the United States is there such willingness to listen to, try out, and evaluate all theories, methodologies, and techniques, and to absorb and find a place for all or many of them. We are also happy to have in our midst a representative number of authors from other countries.

When the first edition was published, it was the first time that a work of this kind appeared in the United States. It was also the first time that some of the topics and issues appeared in a textbook of psychiatry published anywhere. That this Handbook, within a short time, was imitated by other editors in the United States and abroad was proof of its value and a source of rejoicing for us. Perhaps this will happen again, as we hope that the usefulness of the innovations of the second edition will be evident.

It is apparent from the organization of the Handbook that the views expressed in the various chapters are the responsibility of the respective authors and do not necessarily represent those of the editors or the publisher. On the other hand, the single contributors are not responsible for the general editorial policies, with which, in a few instances, they may have disagreed.

As I have already mentioned, this first volume deals specifically with the foundations of psychiatry. Foundations are of various kinds, and they will all be represented in this book. They include the historical background, the very basic notions from which the discipline emerges, the methodology with which

we examine and classify the patient, and the knowledge of the normal life cycle and its common vicissitudes. They also include the theoretical foundations on which the various schools of psychiatry have based their work.

It is not feasible to express gratitude individually to the hundreds of people who, in various ways, have helped prepare this project. Their work will unfold in these six volumes and will speak for itself. I shall mention only that for many years the staff of Rasic Rooks has faithfully cooperated and made it possible to transform into reality what was once only a hopeful expectation.

PART I
History

Chapter 1

Psychiatry From Ancient To Modern Times

Henri F. Ellenberger M.D.

Introduction

Modern psychiatry, like the other branches of science, is continually changing. Today's discovery will soon be made obsolete by tomorrow's discovery. At present certain medical papers mention only the literature of the past five years; the rest is almost as antiquated as Hippocrates. This being the case, one may wonder about the interest of the history of psychiatry and inquire into its meaning.

No science can progress if it lacks a solid theoretical fundament. There is no theory of science without a knowledge of the history of science, and no theory of psychiatry without a knowledge of the history of psychiatry. This becomes evident as soon as one ponders the basic principles of modern psychiatry. Why should we treat mental patients humanely? Is any kind of healing possible without a rational body of knowledge? Is there a difference

between an empirical body of knowledge and a scientific, experimental one? Does psychiatry belong to medicine, or is it a science in its own right, or perhaps no science at all? In order to solve such problems philosophical cogitation is not enough: one needs a great deal of data, and these data can be secured only through historical inquiry. However, this implies in turn that historical inquiry be conducted not in an amateurish fashion, but by means of a scientific methodology.

Unfortunately medical history is a very young branch of science. It is not enough to say that there are wide gaps in our knowledge of Greco-Roman, Arabian, and medieval medicine (not to speak of Indian or Chinese medicine). The truth is that we possess only extremely fragmentary data, so that any reconstruction attempted on the basis of these data is doomed to be artificial. In regard to the last two or three centuries, the difficulty often stems from the immense accumulation of data, so that the trees hide the forest.

Today scientists are keenly aware that no progress can be called definitive, that any discovery can at any moment be displaced by a new one. But we should not overlook another, complementary viewpoint: the progress of today might also get lost through the regression of tomorrow. Science implies not only a striving toward progress but also a constant effort to maintain the permanent acquisitions of yesterday. These are two among the fruitful lessons that a psychiatrist may learn from the history of science.

The Roots of Psychiatry

Although scientific psychiatry is hardly more than one or two centuries old, it is in a large measure the outcome of notions and procedures that are perhaps as ancient as mankind itself. It would seem that from the beginning among all populations of the earth a special attention was bestowed upon certain conspicuous types of behavior or other abnormalities. Individuals whose behavior was deemed to be abnormal were dealt with in three possible ways. Many of them were treated in a downright inhuman, cruel way. Some others were treated in a human but nonmedical way (for instance, those psychotics whose utterances were taken for prophetic inspiration). A third group were submitted to a variety of healing procedures that we today understand to be anticipations of modern psychiatry.

The birth of scientific psychiatry was a long-range process. It started with the discarding of nonmedical ways of dealing with mental patients and the perfecting of primitive healing procedures. The next step was the constitution of systematic bodies of knowledge by medicine men (and later temple healers) and also by lay healers. The third step was the foundation of a rational medical art, severed from religion and superstition; this great revolution is symbolized by the legendary figure of Hippocrates. But whatever its merits, the rational medicine of the Greeks and Romans still remained on a prescientific level (to use Bachelard's terminology). The

foundation of a properly scientific medicine did not occur before the seventeenth century, and that of psychiatry as a branch of medicine in its own right came still later.

In this text I shall attempt to retrace these steps as briefly as so complex a matter will allow. It has been, indeed, a long way from nonmedical attitudes to primitive healing, from primitive healing to rational pre-scientific medicine, and from there to scientific medicine and modern psychiatry.

Nonmedical Ways of Coping with Deviant Behavior and Abnormalities

For countless centuries a great number of those persons who would indisputably be recognized today as mental patients were the victims of social attitudes in direct opposition to the principles of a humane and scientific psychiatry. Feeble-minded infants, with or without bodily defects, were often killed shortly after their birth without further ado. Even among the culturally enlightened Greeks such children were exposed in the wilderness. Among certain Western and Central European rural populations there was a lasting belief in the existence of "changelings." Goblins or demons were supposed to steal newborn children and replace them with their own ugly progeny. Children believed to be changelings were often left without nourishment so that they would die of hunger; this was no crime since these beings allegedly did not belong to humankind. Those feeble-minded children who survived

often were mercilessly exploited by their families, or led a miserable life, being the butt of their community's jokes.

Those senilely demented were often ruthlessly treated. Koty has shown that among the populations of the earth certain peoples are kind and considerate with old people and cripples; others harsh and cruel. But even in the best case these individuals were likely to be sacrificed in the eventuality of famine or other calamities.

Psychotics frequently fled from, or were rejected by, their communities. Some of them, the stronger, would escape to the woods or desert places, living as "wild men," feeding themselves on roots and berries. An example is the demoniac of Gadara described in the Gospel: he had been tied up several times but had managed to break his chains and escape; he lived in tomb vaults and frightened the surrounding population. When these psychotics attacked passers-by or isolated homesteads, they were outlawed so that they could be killed by anyone without compunction. Less severe psychotics would survive as vagrants and live off the charity of individuals and communities. Accounts from the Renaissance period tell of "fools" roving from place to place; in certain communities they were provided with some food or money and gently led to the border; in other places they were driven away with a whip; no doubt they paid a heavy toll in fatal illnesses or accidents. There are also stories of "fools" being set in a little boat on the river, so that the stream

would drift them along to another place.

A frequent plight of chronic psychotics was a prolonged confinement in dungeons, cellars, or other dark places, either in a prison, a monastery, or a private home. Even after mental hospitals had been established, certain families preferred to have their patients secretly confined in their home, rather than institutionalized. A famous case was that of the *séquestrée de Poitiers* in 1901. Following an anonymous letter, the police discovered that a catatonic woman had been confined by her respected and well-to-do family in a dark room for 24 years in an indescribably filthy condition; neither neighbors nor friends knew of the existence of the woman.

Mild psychotics, especially those with delusions of grandeur, were often the plaything of children and adults, sometimes made the victims of practical jokes or utilized for nefarious purposes. Philo tells the story of a lunatic who lived in Alexandria in the first century A.D. and was the laughingstock of the children. It happened that Herod Agrippa, king of the Jews and protected by Emperor Caligula, visited Alexandria. A group of people of that city, out of hatred for the Jews, staged an insulting mockery by bringing this "fool" into the gymnasium, dressing him like a king, and greeting him with royal honors; this was the onset of an anti-Jewish riot and pogrom. It would be easy to collect numerous instances of disturbed individuals who were victimized in the worst fashions. Sir John Lauder, a young Scotsman who sojourned in

France in 1665-1666, related that in the town of Montpellier a "fool" proclaimed that he had discovered a universal antidote that could nullify the effect of any poison. He proposed to try it on himself. Although it should have been clear that the man suffered from delusions, the pharmacists of the town prepared a poisonous beverage that the man drank together with his own draught, whereupon he died miserably within a few hours.

The worst fate was probably that incurred by the "furious," the agitated and aggressive psychotics. They usually were chained, sometimes with iron fetters, or mercilessly beaten until they quieted down—that is, fell into complete exhaustion. Sometimes they were sandwiched between two mattresses tightly bound with ropes, where they often died from choking. Herodotus relates that Cleomenes, King of Sparta, "was smitten with downright madness" and went striking every Spartan he met with his scepter. He was imprisoned by his kindred and his feet put in the stocks. He asked for a knife, and the servant who kept him did not dare to refuse his order. Cleomenes then cut gashes in his flesh along his legs, thighs, hips, loins, and his belly until he died. If this could happen to a king, one may imagine what would be the condition of a commoner befallen with a similar condition.

As to psychotic criminals, many of them were tried and sentenced as if they had been ordinary, nonpsychotic criminals. But the crime itself that brought the man to trial was all too often the product of the patient's

delusions, or of mass suggestion exerted upon him, if not of false accusations and torture, as happened to thousands of unfortunate women during the witch psychosis of the sixteenth and seventeenth century.

On the other hand, it could happen that the social response was favorable to the patient. Various types of disturbed behavior were tolerated in many cultural settings. Certain mental patients were well cared for by the community. Such was the kind attitude of the poor mountaineers in the high valleys of the Alps toward the feebleminded afflicted with cretinism, a condition that was endemic on these mountains until the middle of the nineteenth century. In certain cultural settings psychotics with delusions of grandeur were honored as prophets; sometimes they gathered followers and launched a psychic epidemic.

One should not be too shocked by such "primitive" attitudes toward mental patients. In our own century did we not see the inmates of mental hospitals being systematically exterminated in certain civilized nations, and left to perish miserably of hunger in other countries? The humane and scientific care of mental patients has been a hard-won, delayed achievement in the history of mankind, a conquest that will always need to be defended against the powers of obscurantism and oppression.

Primitive Healing

As far as we can go back into the past we find evidence that a more privileged group of mental patients benefited from certain healing procedures. About healing in prehistoric times we know almost nothing. Numerous skulls from the neolithic era show the marks of trepanning that had been performed on living individuals and followed with cicatrization. Since even in recent times the same operation was performed by medicine men of various primitive populations as a cure for certain nervous conditions, it is likely that the rationale was the same among our prehistoric ancestors. A few pictures of prehistoric art point to the existence of magic and wizards. Such is the well-known picture of a sorcerer, his head adorned with deer's antlers, in the "Cave of the Three Brothers" in southern France, a picture believed to have been painted about 15,000 B.C. and to be the oldest known representation of a healer.

We assume that a continuity exists between prehistoric and primitive healing, such as it is known from ethnological inquiry. Unfortunately many primitive populations disappeared before any serious study could be conducted, and of those that survived many retained only distorted remnants of their former medical lore. However, the systematic study of primitive medicine, undertaken by Buschan, Bartels, and their followers, provides us with a fairly accurate knowledge of the main features of primitive medicine.

According to Sudhoff, primitive medicine always and everywhere

distinguished several kinds of disease, of treatment, and of healer. Certain conditions, obviously the effect of accidents, parasites, or poisons, suggested the use of rational, empirical treatments (this was *natural medicine).* Instances of death rapidly following hemorrhage or asphyxia led to the belief that the source of life was in the blood or the breath; this was the starting point of *speculative medicine.* Acute sickness or death occurring in an unexpected, inexplicable way was attributed to the action of evil spirits or wizards; this was the foundation of *magical medicine.* Hysterical or epidemic possession incited efforts to expel the mysterious intruder from the soul, and this was *demonological medicine.* Natural medicine was the realm of the "lay healer"; magical and demonological medicine the preserve of the medicine man, later of the priest; speculative medicine was to become the field of election of the rational prescientific physician.

The medicine man plays an essential role in his community. He is not only healer but often a dreaded wizard and one of the leaders of his tribe, along with the priest and the chief. He is a "man of high degree" (as Elkin termed the Australian medicine man), and he has undergone a long and difficult training that often includes the experience of an initiatory illness. His personality is the principal agent of the cure, provided that the patient, the healer himself, and the community are all convinced of his healing power. Thus, his healing methods are essentially psychological in nature. Primitive healing is almost always a public procedure, a ceremony conducted within a

well-structured group.

Ethnologists distinguish several basic disease theories, each one linked to a specific healing procedure: these include the loss of the soul and its recovery by the shaman, the intrusion of a supposed disease object and its extraction, the intrusion of an evil spirit and its expulsion (mainly in the form of exorcism), the breach of a taboo and its propitiation, the pathogenic effect of magic and its cure through countermagic. These procedures are of great interest for transcultural psychiatry, comparative psychotherapy, and medical history. A direct continuity can be shown from exorcism to magnetism, magnetism to hypnotism, and from hypnotism to the newer dynamic therapies.

On the other hand, historians of medicine have convincingly shown that the true ancestor of the modern physician is the lay healer, whereas the medicine man is the ancestor of the priest, who was the physician's antagonist for centuries. Thus, the discontinuous line of evolution led from primitive healing to priestly healing, from there to rational pre-scientific therapy, and eventually to scientific psychiatry.

Priestly and Religious Healing

Around 4,000 B.C. the first kingdoms and empires were founded in Asia and in Egypt. This implied the advent of a new type of social organization

with a large administrative system and of religions with colleges of priests and elaborate rituals. The medicine man gave way to the priest, whereas the lay healer became the physician, although the separation was not always very sharp. For many centuries the healing priest and the physician lived side by side, the physician more concerned with natural therapy (massage, dietetics, hot baths, nonmagical drugs), and the priest with psychological healing.

The healing powers of the priest were enhanced by the fact that, in addition to the attributes of the medicine man, he acquired the awesome prestige of being the representative of a healing god. A few healers came to be considered supernatural beings and gods. Such is the story of Imhotep in Egypt. He was born around 3,000 B.C. and became vizier of Pharaoh Zoser and chief of ritual. Special honors were conferred upon him after his death; later he was worshiped as a demigod; around 600 B.C. he had reached the status of a god of medicine. Numerous wonderful cures were reported to occur at his shrines, and it seems that a medical teaching was provided in his great temple at Memphis. Until about 500 A.D. he remained one of the most popular gods in Egypt.

It would seem that a similar evolution took place in Greece with Asclepius (Aesculapius) though we lack reliable information about his life. In the *Iliad* he is referred to as a physician and father of two physicians. A few centuries later he was a god and numerous patients flocked to his shrines, the

Asclepeia. Most famous were his temples in Epidaurus, Pergamon, and Cos. The beautiful site, the prestige of the place, the stories of wonderful cures, the journey, the period of waiting, all affected the patient. An *Asclepeion* combined the holiness of a place of pilgrimage like Lourdes with the enjoyments of a fashionable health resort. After careful screening the patient had to undergo a period of purification and to perform preliminary rites. The highlight was the *incubation,* that is, the night of sleep in the sanctuary, either on the ground or on a couch called the *kline.* Then the patient might experience an *epiphania* (apparition of the god), or receive an oracle, or have a therapeutic dream, that is, a specific kind of dream that would in itself bring the cure. The cult of Aesculapius did not recede before the advent of rational medicine. As time went on, the number of his shrines increased throughout the Hellenistic and the Roman world, and for some time Aesculapius was a great rival of Christ. After the triumph of the Church, patients sought healing at the new Christian shrines. It is significant that in 1893 the skeptical Charcot wrote a paper *On Faith Healing,* declaring that he had seen patients cured at Lourdes after medical treatment had failed, so that the existence of powerful, unknown healing agents must be assumed.

The influence of religious healing extended over the patients' perception of their own illness. Depressive conditions became linked with the idea of sin; this was particularly marked in the Egyptian and Assyro-Babylonian worlds. Healing could be obtained through confession,

propitiation, that is, reconciliation with the gods, and acceptance of the cosmic order. Concepts of the nature of man, as taught by the priests, also influenced the clinical pictures. One instance is the *Dialogue of a Life-Weary Man with His Soul,* an Egyptian writing of about 2,000 B.C. that might be considered the oldest known document on the psychology of suicide.

Rational Prescientific Medicine

A decisive step in the history of medicine was taken with the rise of autonomous schools of medical practice and teaching, dominated by astute clinicians and creative thinkers. In Egypt the Ebers Papyrus (of about 1,500 B.C.) is one of the oldest documents of this type of medicine. Similar developments took place in Assyro-Babylonia, Persia, India, China, Japan, and even in Mexico among the Aztecs; however, our knowledge of the history of medicine in these countries is extremely imperfect. Modern scientific medicine is predominantly the tributary of Greek prescientific medicine, even in its terminology.

Ancient Greek medicine was based on dogmatic concepts that survived for about 25 centuries. In the same way as Greek priestly medicine was dominated by the mythical figure of Aesculapius, Greek rational prescientific medicine is dominated by the hardly less mythical figure of Hippocrates.

All we know of Hippocrates (about 460 to 377 B.C.) is that he was one

among several reputed physicians of his time; the rest is legend. The treatises collected under his name about three centuries later were divergent in style, dialect, and content. As Werner Jaeger says, "The result of one century of research is that there is not one page in the Hippocratic collection which we can, with certitude, ascribe to Hippocrates himself." Nor do we have his portrait; but his name is traditionally attached to a noble bust that is, in Singer's words, "an idealized representation of what the Greek would wish his physician to be." Whereas the god Aesculapius stood high above mankind, Hippocrates remained the more accessible figure of the "physician-philosopher." To quote Singer again:

> His figure, gaining in dignity what it loses in clearness, stands for all time as the ideal physician. . . . Calm and effective, human and observant, prompt and cautious, at once learned and willing to learn, eager alike to get and give knowledge, unmoved save by the fear lest his knowledge may fail to benefit others . . . incorruptible and pure in mind and body. ... In all ages he has been held by medical men in a reverence comparable only to that which has been felt towards the founders of the great religions by their followers.

Hippocrates is customarily called the Father of Medicine. Before him, however, Greek medicine had at least two centuries of intensive development in the form of autonomous schools of philosophical medicine, and many medical treatises, now lost, had been written. To quote Neuburger: "We stand as in a devastated town, where only *one* building is extant, and we see only the rough outline of the streets." Among these schools the Cnidian strove to diagnose diseases and localize their seats, whereas the school of Cos was

more concerned with the prognosis, with the organism as a whole within the environmental setting, and with the concept of the "healing power of Nature."

It would be irrelevant to speak of a "Hippocratic psychiatry." Throughout the whole Greek and Roman literature, mental disorders are described in one among several other chapters of medicine; nothing is known about that could resemble a textbook of psychiatry. The Hippocratic writings describe or mention three main mental conditions: phrenitis (acute mental disorders with fever), mania (mental disorders with agitation without fever), and melancholia (chronic mental disorders without fever and agitation). A variety of organic paroxysmal conditions in women are related to the uterus (in Greek, *hystera*, hence the adjective "hysterical" which meant "uterine" and did not have the connotation of a neurosis). A description of the "Scythian disease" refers to an instance of transsexuality in the setting of a particular culture.

The Hippocratic writings are often considered the beginning of scientific medicine. To be sure, they discard religion and superstition and strive to rely upon clinical observation, experience, and sound judgment. In this sense it is a rational medicine. However, we are still very far from the principles of scientific medicine. Hippocratic thinking belongs to the pre-scientific level of medicine. Robert Joly has shown conclusively how even the best treatises of the Hippocratic collection are pervaded with "substantialism," "numerology,"

and other irrational elements that often interfere with and blur the otherwise acute clinical vision of the writer.

Greek medicine worked with the principles of physical qualities, the four humors, the pneuma, the faculties of the soul, and organic localization. These principles had to be correlated to each other and with the clinical pictures offered by medical practice.

Greek philosophers had widely discussed polarities of opposite qualities. The two main polarities finally chosen were those of dry-moist and warm-cold. Philosophers had also argued endlessly about the physical elements until Empedocles settled the question by compromise, proclaiming as the fundamental elements water, air, fire, and earth. Similarly physicians decided there were four humors of the human body: phlegm, blood, bile, and "black bile." Like the four elements, the four humors were correlated to the physical qualities (phlegm moist-cold, blood moist-warm, bile dry-warm, black bile dry-cold). Morbid conditions were explained by the resulting imbalance from the excess of one of the humors. Thus, *melancholy* was thought to result from an excess of black bile. However, it soon became necessary to involve also changes in the qualities of the humors, disturbances in their circulation, and to distinguish varieties among each one of the humors.

Meanwhile, primitive medicine's concept of breath (or pneuma) as a principle of life had found its way into philosophical medicine. Stoic philosophers and the Pneumaticist school of medicine distinguished three kinds of pneuma, physical, vital, and psychic, and interpreted certain diseases as resulting from a lack or alteration of the pneuma.

Greek concepts of the soul, originating in primitive and priestly medicine, were developed by the philosophers. Aristotle distinguished three main "souls" of the human psyche: vegetative soul (common to plants, animal, and man), animal soul (common to animals and man), and rational soul (property of man only). To each one he attributed several "powers" (or faculties). The use of this framework led to associating mental states with lack, excess, or disturbance of the various "souls" or "powers." Passions were considered excessive activities of the animal soul, or the absence of control over the animal soul by the rational soul. Certain mental conditions were supposed to result from a deficiency of the rational soul (anoia).

Greek philosophers and physicians argued about the seat of the soul and of its faculties. The ancients had thought that the diaphragm (*phrenes)* was the seat of the soul, hence the word "phrenitis" for acute fever delirium (this condition later was correlated to an inflammation of the brain or its coverings). As to the seat of the intellect, Empedocles, Aristotle, and Diodes said it was the heart, whereas Alemaeon, certain Hippocratic writers, and the

Alexandrian, Galen, held for the brain. The next step was the localization of the various "souls" and "powers."

We can see how heterogeneous were the theoretical assumptions underlying Greek psychopathology. The word "melancholia" was derived from humoral pathology, "anoia" from psychological concepts, "phrenitis" from supposed anatomic views, whereas the word "mania" (probably a colloquial word) simply meant "madness" or "fury." Epilepsy, a purely clinical designation, expressed the main symptom of the convulsive attack. The Hippocratic writers had inherited this terminology from their unknown forebears, and the whole development of Greek medicine was a ceaseless effort to integrate these various conflicting concepts and clinical pictures into a coherent system.

The legacy of ancient Greek rational medicine is thus a twofold one. Greek medicine gave to the world the ideal figure of the Father of Medicine, Hippocrates. On the other hand, it gave also an abstruse, increasingly artificial system of dogmatic medicine, which predominated throughout Hellenistic, Roman, Arabian, and Western medicine and eventually became an intolerable burden that impeded the progress of human thinking.

Psychiatry in the Greco-Roman World

In the Greek and Roman worlds there was no such thing as "psychiatry"

as we know it today, but only a few scattered elements of that which was to become this science much later.

We have discussed the prescientific concepts utilized by Greek rational medicine. The Greek physician's way of thinking was not less different from ours. The modern scientist starts with observation and quantification, draws inductions and hypotheses that are tested by experimentation and according to the findings accepted or rejected. Not so with the Greeks, who used axiomatic thinking, started with statements considered self-evident, then drew deductions that they extended with the help of analogies. Conflicting statements were rarely submitted to experimental testing, but mostly settled by theoretical discussions and compromises without much regard to facts.

In Greek science there was no unified framework universally accepted and adopted by all scientists. Instead, there were a number of schools based on particular philosophical systems, each one professing its own dogmatic teaching incompatible with those of the other schools. Greek medicine remained inseparable from philosophical speculation. Each philosophical revolution had its counterpart in medicine: the Pneumatists based their system on Stoicism, the Methodists on Epicureanism, the Empiricists on Skepticism. The movement toward philosophical syncretism was paralleled by the medical eclecticism of Galen.

It would be fascinating if we could closely follow the evolution and vicissitudes of these medical schools. Unfortunately our knowledge is extremely fragmentary. Out of a thousand books written by the Greeks, hardly more than one or two have survived.

Among the oldest medical schools known to us were those of Sicily, of Cnidos, and of Cos, the latter two well-represented in the so-called Hippocratic writings. Then in the fifth century B.C. Athens became the center of Greek culture. Aristotle exerted a great influence on medicine. He edited an encyclopedic collection of monographs covering the whole field of contemporary learning; there was, for instance, a *History of Medicine* by his pupil Menon, of which fragments have survived. Diodes of Carystos, who was associated with that school, was considered one of the greatest Greek physicians; unfortunately his works are lost. However, his description of hypochondriac disturbances was to be taken over by Galen.

After the Macedonian conquest, the Eastern Mediterranean world was Hellenized and a new cultural center flourished in Alexandria, with its famous museum and library. Among the great Alexandrian physicians were Herophilus and Erasistratus. Both of them made discoveries in the field of anatomy, especially in regard to the nervous system. It is generally assumed that with these two physicians Greek medicine reached its highest scientific level, even though their theories were not free from speculation. Undoubtedly

their works, had they survived, would hold great interest for the history of neurology and psychiatry.

The Empiricists school, whose philosophy was inspired by the Skeptics, was represented mostly by Heraclid of Tarent. They were good clinicians who strove to define diseases according to their seats and described them *a capite ad ealeem,* that is, going from scalp and hair down to the heels and adding a chapter for general diseases. Mental diseases were classified among the diseases of the head, following those of the scalp and the skull. This type of classification was traditional up to the seventeenth century.

Inspirer of the Methodist school was Asclepiades (first century B.C.), a fashionable Greek physician and prolific writer who practiced in Rome. His works have been lost. He seems to have been much interested in mental diseases and to have applied a variety of treatments: hydrotherapy, gymnastics, massage, suspended bed, music therapy—obviously a therapy accessible only to a few wealthy patients. Another great Methodist physician, Soranus of Ephesus (first half of the second century A.D.), discussed the treatment of mental diseases along the same lines as Asclepiades. Most of his writings have perished, but something of his work is known thanks to a Latin adaptation by Caelius Aurelianus.

Another school, the Pneumaticists, basically followed the philosophy of

Stoicism and emphasized the doctrine of the pneuma. Their great proponent was Archigenes; his works are lost but were utilized by Aretaeus who flourished around 100 A.D. Aretaeus gave clear descriptions of the traditional disease entities, phrenitis, mania, and melancholia, and mentioned that mania and melancholia could turn into each other. This simply meant that a chronic psychosis could begin or be interspersed with acute episodes.

The Romans did not found a school of medicine, but compiled encyclopedias embracing the whole field of knowledge. Those by Cato and Varro have perished, but we have the medical part of A. Cornelius Celsus' encyclopedia (first century A.D.) with a chapter on mental diseases. Among the treatments were fettering, flogging, starving, or terrifying the patient, and suddenly pouring cold water over his head; however, rocking the patient in a suspended bed was used in other eases.

The eclectic trend was personified by Claudius Galen (ca. 138-201 A.D.), an outstanding clinician, good investigator in the field of physiology, and passionate systematizer. He borrowed his philosophical principles from Aristotle, the Stoicists, and the Hippocratic writers. A prolific author, he is credited with writing about 400 treatises, of which about 80 are extant. Because the works of the most prominent physicians before and after him have been lost, Galen towers as a mighty isolated genius. He endeavored to reconcile his clinical and experimental findings with the traditional doctrines

of the qualities, the humors, the pneuma, the "powers" of the soul, and the localizations. Galen laid great emphasis on the doctrine of the four basic humors, which had been much developed since the Hippocratic writers. Disease resulted from the excess of one humor and the resulting dyscrasia (imbalance), or from mixtures and alterations of the various humors, or from their accumulation in pertain organs, or from the ascension of "vapors" from the stomach or other organs to the brain. Galen's humoral doctrine covers also the field of the innate constitutions or temperaments. Galen distinguished two kinds of black bile. The word "melancholia" could mean either a specific variety of innate character or one among a wide range of diseases caused by the action of the two kinds of black bile. The Galenic doctrine extended to the theory of drugs and their therapeutic indications.

On Melancholia, a treatise under Galen's name described three main forms of this condition: (1) general melancholia (from an excess of black bile in the whole body), (2) brain melancholia (from an excess of black bile in the brain), and (3) hypochondriac melancholia (from the ascension to the brain of vicious vapors from the stomach). The author refers also to constitutional melancholia, melancholia from a one-sided diet, from the "adustion" of yellow bile, from the suppression of hemorrhoidal or menstrual flux, from precipitating emotional factors. Finally he describes particular clinical types of melancholia, one of them being *lycanthropia,* that is, the delusion of being transformed into a wolf. This treatise standardized for the following fifteen or

sixteen centuries the concept of melancholia. It was the model and prototype of a tradition that was to culminate with Robert Burton's *Anatomy of Melancholy* in 1621.

It is usually assumed that Greco-Roman medicine underwent a swift decline after Galen. This might partly be an illusion resulting from the fact that the works of the most original minds of the following few centuries have been lost. Posidonius (second half of the fourth century A.D.) seems to have been eminent in the fields of neurological and mental diseases. But the Roman Empire was crumbling under its inner weakness and the repeated assaults of the barbarians, and medical progress was hampered. Thus, Galen was resorted to as the infallible oracle who had said the final word about medicine.

One may wonder to what extent the patients actually benefited from the kind of medical care expounded by all these authors. Greco-Roman physicians were mostly interested in acute diseases; they gave up the care of chronic patients as soon as these appeared to be incurable. Medical care was mostly given to patients of the upper classes in the cities and to the military. According to George Rosen, the family and friends of the Greek and Roman patients were expected to provide for them according to the accepted customs, and the condition of the insane poor was extremely miserable.

There were apparently a few privileged forms of mental disorders. Plato distinguished "divine madness" from natural madness. Divine madness included the four varieties of prophetic madness (given by Apollo), religious madness (given by Dionysus), poetic madness (inspired by the Muses), and erotic madness (inspired by Aphrodite and Eros). An unclear problem is the feigned madness of men such as Meton, Solon, and Brutus: it would seem that it was a kind of ceremonialized eccentric behavior conspicuously displayed in certain extraordinary circumstances in order to focus attention upon an impending public danger.

Throughout the ancient world there were a few practices that could deserve the name of psychotherapy. Specific techniques of mental training were associated with the philosophical schools. The Pythagorians practiced exercises in self-control, memory recall, and memorization for recitation. The Stoics learned the control of the emotions and practiced written and verbal exercises in meditation. The Epicureans resorted to an intensive memorization of a compendium of maxims that they recited ceaselessly, aloud or mentally. Psychological training could be individualized as evidenced by Galen's treatise *On the Passions of the Soul.* This method consisted of unceasing effort to control one's passions with the help of a wise mentor who would point out one's defects and dispense advice, then the gradual reduction of one's standard of living, attaining serenity and freedom from affects, until one was able and ready to help others in a similar way.

Lain Entralgo has pointed out the importance of the "therapy by the word" among the ancient Greeks. There was a cathartic, a dialectic, and a rhetorical use of the spoken word. One particular practice was the consolation, a letter, sometimes a poem, written to a person suffering grief and intended to help him recover peace of mind. Several of these consolations have become literary classics, such as Plutarch's *Consolation* to his wife for the death of their child, or his *Consolation* to his friend Apollonius for the death of his son. This kind of supportive psychotherapeutic intervention was to revive in Western Europe in the sixteenth and seventeenth century.

The Romans are credited with founding public hygiene. They devised elaborate systems of water adduction and sewage. A slow development of public medicine took place: there were town physicians paid by city authorities and a rudiment of medical teaching. But their only hospitals were the *valetudinaria* for the recuperation of wounded soldiers, gladiators, or slaves. Their moral callousness, their predatory economy, the use of vast masses of miserable slaves, the cruel games of the circus, all these were the antipode of any kind of mental hygiene.

Christianity no doubt introduced a new spirit. Its founder imposed the care of the sick as a religious duty. Charity institutions and hospitals gradually developed, parallel to the flourishing of monasteries. Christianity influenced much of the philosophical and legal thinking, and the practice of religious

confession stimulated the development of introspection: this is well illustrated by Saint Augustine's *Confession.*

Psychiatry in the Middle Ages

After the ruin of the ancient world, Greco-Roman culture split into three parts: the Byzantine Empire, the Arabia, and Western Europe, each with its vernacular language: Greek, Arabic, and Latin. Each developed its own civilization and medical tradition, but they were bound by certain mutual influences.

Although the barbarians had destroyed the Western Roman Empire, the Eastern Roman (or Byzantine) Empire survived for ten centuries, and its capital, Constantinople, became the cultural center of the world. In the sixth century A.D., under Emperor Justinian, many charitable institutions were founded, such as orphanages, homes for the aged, and hospitals, among which were a few *morotrophia* for the mentally sick. Unfortunately we do not know how these institutions functioned and what vicissitudes they underwent between the sixth and the fifteenth century. What could be the way of life of an insane person in Constantinople is shown by the descriptions we have of the *saloi* or "sacred fools": these men led an utterly marginal life, living off the charity of good people, being an object of ridicule, but enjoying the privilege of telling the truth to anybody. The Greek medical tradition was prolonged by

men such as Aetius of Ami da and Alexander of Tralles (sixth century), Paul of Egina (seventh century), and Johannes Actuarius (fourteenth century). Contributions of psychiatric interest could probably also be found among the writings of Byzantine theologians and writers: to give only one instance, Eustathius of Thessalonica (twelfth century) wrote a treatise, *On Simulation,* analyzing role playing in the theater and in life and giving a psychology of histrionism. But numerous precious works perished in the catastrophe that engulfed Byzantine civilization in 1453.

In the seventh century the Islamic invasion destroyed Hellenistic civilization in Asia Minor, Syria, and Egypt. Then, after the Arabs had conquered an empire stretching from Persia to Spain, they underwent the influence of the conquered countries, and by the late eighth century and during the ninth century a brilliant Islamic civilization flourished in Baghdad, Cairo, and Spain. It was an era of widespread development for a medicine based on the teachings of Hippocrates, Galen, Aretaeus, and the earlier Byzantines. But here, too, it is difficult to appraise the real originality of that period. Out of a thousand books written by Arabian physicians, very few have survived; among these few most either remained in manuscript or were not translated into modern Western languages.

Among the most outstanding names one should mention Rhazes (864-925), a Persian distinguished in all fields of medicine. Among his many

treatises is one translated into English under the title, *The Spiritual Physick of Rhazes:* a classification of psychopathological disorders is given, according to the failure or excess in each one of the three "souls" (vegetative, animal, and rational). Rhazes also discusses drunkenness (a topic somewhat neglected in extant Greek medical books) and its motivations: to dispel anxiety, to meet situations requiring particular courage and cheerfulness. Arabian medicine culminated in the work of Avicenna (989-1037), a Persian poet, philosopher, and physician, whose *Canon of Medicine* was used as a medical textbook for centuries in the Islamic as well as in the Western European world. The *Canon* systematized the highly artificial concepts enounced by Galen. The diseases are described in the traditional order "from head to heels," mental diseases being included in the chapter on head diseases. Arabian literature, like the Byzantine, contains nonmedical works that are of interest for the psychiatrist, for instance, books by the mystics, the moralists, the philosophers, books on physiognomy, on the interpretation of dreams. But of all this wealth, the greatest part has perished, and very little of value is available from the rest.

Throughout the Islamic world, many mental hospitals were founded by pious benefactors, especially in the thirteenth century. Among these were *moristans,* most probably inspired by Byzantine *morotrophia.* We have wondrous descriptions of the great hospital in Cairo in the thirteenth century, and especially of the *moristan* of Adrianople (Edirne) founded in the fifteenth century. In the midst of paradise gardens was a luxurious marble building

with fountains in the courts, summer and winter rooms; the patients lay on silk cushions, were nourished with the finest food, were treated with a combination of drug, music, and perfume therapy, received friendly visits from the beauties of the town; their chains were gilded with gold and silver. In sharp contrast with such a description, we read in a poem of Djelal-Eddin (thirteenth century): "In the corner of a dungeon sat a raving insane; his neck tied with a rope." The French traveler Chardin, who visited Persia in the seventeenth century, describes the *moristan* of Ispahan as a kind of cloister around a garden; there were about 80 cubicles, but only seven or eight lunatics, all of them in the most miserable condition, lying on straw, fettered by arms, body, and neck. The staff consisted of one doctor, one pharmacist, one *molla* (priest), one cook, one doorman, and one cleaner. Not much better is the account given by Edward Lane of the *moristan* in Cairo in the middle of the nineteenth century: there were two courts, one for male and one for female patients. Around the first court were 17 very small cells with grated windows. The patients were chained by the neck to a wall, had only straw to sleep upon, and wore scarcely any clothing. It was customary for each visitor to give them pieces of bread, so that as soon as they saw a stranger enter, they made a great clamor. Obviously the Cairo *moristan* had declined since the thirteenth century. Actually we know very little about the history and the functioning of the Islamic mental institutions.

After the ruin of the ancient world, medicine in Western Europe was in a

precarious state. There was a long period of destruction and decline. The privileged class of city aristocracy for whom Greco-Roman medicine was meant had disappeared, the writings of ancient authors were lost, medical tradition was interrupted. However, as we have seen, Christianity forwarded the care of the sick. Saint Benedict's rule proclaims that "the care of the sick is to be placed above and before every other duty." There were infirmaries in the monasteries, where monks made use of medical compilations written by obscure authors.

Meanwhile, the Church slowly gathered a certain amount of psychiatric knowledge of its own. In monasteries and in the practical experience of the confessors, certain specific conditions had been observed: the *acedia* (boredom) of the monks, the *scrupulositas* (excessive scruples) of certain penitents. Later the distinction between genuine and false mysticism and other observations made by moral theologians were the objects of valuable inquiries. Not until our time, however, were they incorporated, as a section of "pastoral psychology," in the general body of psychiatry. On the other hand, demonological concepts were taken for granted by the Church and accepted by medicine. In view of the general belief in demonology, many cases of neurotic or psychotic disturbances took the form of devilish possession, and conversely many patients could be cured by exorcism. Suggestive healings also took place at the shrines of certain saints; patients could sometimes remain there for a prolonged time; this was the origin of the psychiatric

colony in Gheel, Belgium, which still exists and can be traced back to the thirteenth century.

Gradually there was a revival of lay medicine and a rise of medical schools. The thread with ancient Greco-Roman medicine was found again. After the recovery of Galen's works, his system became in its whole complexity and artificiality the official doctrine of Western European medicine.

Another great event took place in the thirteenth century. As in the first centuries of Christianity, the cure of the sick was placed in the foreground of Christian duties, and many hospitals were created. There are reports on hospitals for the mentally sick scattered in several European countries; however, the main development took place in Spain. In Granada an asylum for the insane had been founded by the Moorish King Mohammed V in 1365-1367, and the plan of the older Spanish asylums copied the plan of the Arabian *moristans.* The first one was opened in Valencia in 1407 under the name of *los Desamparados* (the abandoned) by Father Jofre, and operated by an association of 100 clerks, 300 laymen, and 300 lay women. Then came the foundation of the asylums of Saragossa in 1425, Seville in 1436, Barcelona in 1481, and Toledo in 1483. Spanish historians, notably Juan Delgado Roig, have published the acts of foundation and official documents of these hospitals, but many details about their functioning are still unclear.

Psychiatry in the Renaissance Period

Appraisals of the Renaissance have varied. According to Jacob Burckhardt, it was the period of "coming into awareness of the human personality, of its nature and place in the universe." Man's image of the world was immeasurably widened following the geographic explorations and the rediscovery of ancient Greco-Roman culture. Man became able to perceive reality instead of what he had been taught to see. G. de Morsier, a historian of brain anatomy, has shown that fourteenth- and fifteenth-century surgeons who dissected human bodies were unable to see anything except what Galen and the Arabs had taught; the ability to perceive the anatomy of the brain as it is, and not as one believes that it should be, appeared in the early 1500s almost simultaneously and independently from each other in men born in Italy, France, Belgium, and Holland. The death blow to Galenic anatomy was given by Vesalius in 1543. The same transformation occurred in botany, astronomy, physics, and other sciences. These innovations, however, met much resistance from the adherents of the traditional doctrines. In addition to these great advances, the Renaissance was also the period when slavery (which had been abolished since the fall of the Roman Empire) was reestablished, at least in the newly conquered colonies, when widespread genocide took place in the Caribbeans and Central America, when judicial torture was reinforced under the impact of resurgent Roman law, and when the witch psychosis underwent an unprecedented development. Another

negative feature of the Renaissance was its contempt for the vulgar, the illiterate, and the "fool." But there was much interest in mental illness and in the multiform manifestations of *imaginatio*, a notion that included all that we call today suggestion and autosuggestion as well as many creations of the unconscious mind.

Medical authors of the Renaissance are much better known than those of previous periods because the invention of printing gave their works a better chance to survive. In Italy Arturo Castiglioni praises the psychiatric writings of G. R. da Monte, Gerolamo Mercuriale, Prospero Alpino (all three mainly interested in melancholia), and Jerome Cardan (a precursor of the concept of moral insanity). One should also mention Jean Fernel in France, Johannes Schenck in Germany, and Timothy Bright in England. The latter's *Treatise of Melancholie* (1586) is considered the first psychiatric book written by an Englishman. His theory of melancholia was also highly successful in the literate world, and this may explain the great popularity of Robert Burton's *Anatomy of Melancholy* (1621). Although Burton admits that the distinction of the various subforms of melancholia is "a labyrinth of doubts and errors," he describes them in detail. Melancholy became the fashionable disease in England. The type of character that was moody, cold, bitterly ironic, eccentric, misanthropic, disgusted with life, and predisposed to suicide became identified with the term "melancholy," later called spleen or hypochondriasis, and on the continent it was sometimes considered to be the typical English

character.

The break with the tyrannical domination of the Galenic system in medicine was effected mainly by two great pioneers, Paracelsus and Platter. Theophrastus Bombastus von Hohenheim, called Paracelsus (1493-1541) is perhaps the most problematic figure in the history of medicine. Many episodes of his wandering life are tinged with legend. He has been considered a quack, a paranoid schizophrenic, a genius, a mystic philosopher, an initiate to secret sciences, a precursor of the psychology of the unconscious, an eminent psychotherapist, a pioneer of modern medicine, or a mixture of all these. Few authors are more difficult to read and more untranslatable. Sigerist says that "perhaps no one but a German can really understand him." His writings are an incoherent succession of abstruse philosophical concepts, abuse against his enemies, affirmations based on his belief in astrology, alchemy, witchcraft, and other superstitions, interspersed with good medical insights or striking aphorisms: "The highest foundation of medicine is love"; "What the Greeks have told is not true for us; every truth originates in its own country"; "Do not hold the effect of curses as nonsense, ye physicians, ye have no inkling of the power and might of the will"; "The child needs no star or planet: his mother is his planet and his star." On the positive side are Paracelsus' teaching of a new pharmacology based on the use of mineral substances (sulphur, antimony, mercury, and others), his emphasis on the effects of suggestion, his belief in the efficacy of healing springs, his interest in

occupational diseases of the miners, his concern for cretins and other feeble-minded persons ("Fools are our brethren; like us they were saved by Christ"). Paracelsus died prematurely, leaving few adherents and no organized movement; a great part of his writings were lost or remained unpublished. He had the good luck to find almost four centuries after his death an admirer, Karl Sudhoff who published his extant works. But Paracelsus had already become a legendary figure and was made the hero of novels and theatricals. The (true or fictitious) story of his spectacular burning of Galen's works on the public place in Basel in 1527 acquired a symbolic value and was paralleled with Luther's burning of the papal bull on the public place in Wittenberg. It is ironic that Basel, where Paracelsus had failed, was the home of another medical reformer, Felix Platter (1536-1614), who carried out some of the reforms vainly attempted by his predecessor.

Platter's life is better known than most physicians' because he left his autobiography, his almost lifelong diary, his correspondence, the catalogue of his collections, and all of his writings. He studied medicine in Montpellier and lived the rest of his life in Basel. He became a brilliant practitioner who was called as a consultant to kings and princes; as a teacher he made the University of Basel famous and wrote standard textbooks on medicine; as a scientist he advanced Vesalian anatomy, clinical medicine, and psychiatry. In his medical works Platter described diseases exclusively as he had seen them in his practice, never quoting any author, never concealing his ignorance or

his doubts, and giving case histories of his own patients as illustrations. This might seem a matter of course today, but at that time physicians used to follow the descriptions of the old masters, with case histories borrowed from the classics. As Paracelsus had done before him, Platter gave up the old classification of diseases "from head to heels" and introduced a new principle. Platter's descriptions are models of clarity. Each condition is subdivided under three headings: *genera, causae, curatio* (symptoms, causes, treatment). With Platter practical medicine acquires the precision of a scientific discipline; medicine is detached from philosophy and becomes a branch of natural science.

Certain historians of medicine have pointed out that the Renaissance was a period of great suffering for the mentally ill. According to Walsh the hospitals were much better and the insane more humanely treated in the thirteenth century than later. Kirchhof writes that in the Middle Ages great help was provided to the insance by monasteries, brotherhoods, and pilgrimages. Wherever such institutions were abolished by the Reformation, mental patients were abandoned to the harsh treatment of public civilian authorities.

The evil culminated with the witch psychosis of the sixteenth and seventeenth century. The belief spread that witches committed crimes in alliance with the devil and that they had organized a universal conspiracy to

destroy mankind. In order to eradicate the alleged evil, extraordinary forms of prosecution and trial were used. The *Malleus Maleficarum,* a guide for the Inquisitors conducting witch trials, gives a sinister picture of the delusion; its third part amounts to a textbook on the technique of brainwashing. Thousands of women of all ages and walks of life confessed the most improbable crimes. Some of them undoubtedly were neurotic or psychotic, but a great many were normal individuals who accused themselves under the impact of mental and physical torture. Witch hunts, inaugurated by the Inquisition, were pursued actively by lay civilian authorities, Protestant and Catholic alike. Among the few who dared openly to defend the incriminated was Johann Wever (1515-1588). Though sharing himself the contemporary belief in witchcraft, Weyer tried to demonstrate that the supposed witches were victims of the demon rather than his allies. His book contains many interesting clinical cases, but lacks psychiatric systematization. Later Weyer came to be considered a great pioneer of psychiatry and to be called, not without exaggeration, the promoter of the "First Psychiatric Revolution."

Those asylums for the humane treatment of the insane that had been founded in Spain in the fifteenth century were isolated institutions, supported by rich patrons or local authorities. A crucial development began with Juan Ciudad Duarte (1495-1550). A pious and eccentric merchant in Granada, he suffered an acute psychotic episode and was treated in the local hospital with merciless flogging. After his recovery he founded a hospital where patients

were treated humanely; he operated it with the help of a few volunteers. His organization grew; after the founder's death it was declared the Order of the Hospitalers, and Juan Ciudad was canonized as Saint John of God. This Order created and operated general and mental hospitals. All institutions of the Order worked according to the same rules and were run by men trained at the same place, so that experience could be collected and transmitted. These institutions spread over Spain, Italy, France, and other countries. Later they served as models to Philippe Pinel and Jean-Etienne Dominique Esquirol when they devised modern mental hospitals. It is not surprising that the first mental hospital episodes to be found in European literature appear in Cervantes' *Don Quixote.* (Until then mental disease had often been described in poetry, novels, or on the stage, but not the mental hospital.) In one episode of the novel an inmate of the Seville asylum protests to the archbishop that he is unduly retained, whereupon the archbishop sends his chaplain to examine the patient. In Avellaneda's continuation of the first part, Don Quixote is the victim of numerous cruel practical jokes and is treacherously committed in the Toledo asylum; the reader is left to suppose that he will stay there for the rest of his life. This probably brought Cervantes to write the second part of the novel: the hero recovers his sound mind on his death bed; far from being just the victim of ridiculous delusions, Don Quixote now appears as a personification of the human condition.

Early Scientific Psychiatry

The advent of modern science was a slow and gradual process, and it took a long time until it extended to psychiatry. During the Renaissance man had learned to perceive reality as it is and not as it should be; now man attempted to fathom the depths of nature and elicit her laws. This implied the use of new methods, such as systematically conducted experiments and measurement techniques, and of new instruments, such as the microscope. In natural history the principle of specificity came to the foreground. This evolution started at the end of the sixteenth century and developed during the seventeenth and the eighteenth centuries. Among its theoreticians were Francis Bacon and Descartes; among its pioneers Copernicus, Kepler, Galileo, Newton, and Vesalius and Harvey in medicine. But new systems arose, founded partly on science and partly on speculation. Such were iatromechanicism (Borelli, Baglivi), iatrochemistry (Van Helmont, Sylvius), and the "animism" of Georg Ernst Stahl (1660-1734). The latter was to exert a great influence upon German Romantic psychiatrists. Actually seventeenth- and eighteenth-century medicine was a curious mixture of genuine science, loyalty to antiquated doctrines, and new irrational systems—all three often in the same man.

Psychiatry was not yet an independent discipline. However, it underwent a noteworthy evolution. To the extent that Galenism was overthrown, mental diseases ceased to belong to humoral pathology and

were correlated with disturbances of the nervous system; what was formerly attributed to "black bile" began to be labeled as nervous ailments.

Several of the new pioneers of medicine remained staunch believers in Galenism. In Italy Paolo Zacchias (1584-1659), a man eminent both as a physician and a lawyer, gave in his *Quaestiones medico-legales* (1621-1635) an inexhaustible mine of documents and expounded a new system of psychiatric diagnosis. He is generally considered the founder of forensic psychiatry. In England Thomas Willis (1622-1675) was, in spite of his belief in Galenism, a keen clinician and indefatigable experimenter who made outstanding discoveries in the anatomy and physiology of the nervous system. He integrated neurology and the study of the neurovegetative system into psychiatry.

Among the new trends was that of the systematists. Sydenham had emphasized that infectious diseases are specific entities: they exist in their own right independently of the sick individuals they affect. Efforts were made to work out an allover classification of diseases in natural species, genera, and classes. The first attempt was probably that of Frangois Boissier de Sauvages (1706-1767), who taught botany and medicine in Montpellier. An outline of his system appeared in 1732 and was considerably enlarged in his *Nosologia methodica* published in Latin in 1763 and in French in 1770. Diseases were divided into ten classes. The bulk of mental diseases belonged to Class VIII,

divided into 4 orders and 23 genera. Among the latter, melancholia contained 14 species. Each species was illustrated by short clinical descriptions, either from Boissier's practice or from other authors. Clinical documents were gathered from every possible source, even from travelers, so that the Malayan "running amok" was incorporated into a European textbook. Boissier's work was far from being a tedious catalogue of diseases; there were lucid introductions to the whole book and to each part; it was written in a clear and flowing style and filled with interesting facts. No wonder it inspired a long series of successors, among them the Swedish naturalist Carl Linnaeus, the English physician William Cullen (who coined the term "neurosis"), and eventually Philippe Pinel. In spite of the artificial character of their classifications, the systematists exerted a useful influence on the development of medicine (including psychiatry). They advanced the practice of looking more attentively for new diseases and facts and organizing material in a more accurate and comprehensive way. It sufficed to replace the terms "classes," "genera," and "species" with "parts," "chapters," and "paragraphs" to obtain the pattern of the nineteenth-century textbooks.

A powerful trend toward rationalism developed under the impact of the cultural movement called the Enlightenment. It forwarded the cult of reason, the concept of society as created for man, and the belief in science. Typical is Voltaire's definition of the word "folie" (insanity) in his *Dictionnaire philosophique:* "A brain disease that keeps a man from thinking and acting as

other men do. If he cannot take care of his property he is put under tutelage; if his behavior is unacceptable, he is isolated; if he is dangerous, he is confined; if he is furious, he is tied." We see here mental illness equated to brain disease, its clinical picture to intellectual disorders, its treatment to the protection of society. In view of the opposition of rationalism to any kind of superstition, the belief in demons and witches gradually receded; demonomania ceased to be considered a preternatural condition and was understood as a man's delusion of being possessed; the term "obsession" lost its meaning of being assaulted by evil spirits and took on its present meaning. La Mettrie, in his book, *L'Homme machine* (1748), contended that certain hard criminals (later called the "moral insane") should be considered sick individuals.

The concept of the unconscious (if not the term) appeared with Leibniz's discussion of the "small perceptions." However, there had already been many observations on the unconscious activities of the mind, even among rationalist philosophers. Descartes wrote in his treatise, *Les Passions de l'ame* (1649), that unexplained aversions may originate from occurrences in early childhood: the event is forgotten, the aversion remains. In another place Descartes told of his propensity for falling in love with cockeyed women and how, thinking about it, he remembered that as a child he had been in love with a young girl who had that defect; after he had understood the connection his predilection disappeared. However, it did not occur to him nor to anybody

else that such observations might be utilized for mental healing. Some kind of rational psychotherapy existed in the guise of consolations, exhortations, and admonishments. There also were various other attempts. Diderot relates how the wife of one of his friends was afflicted with the vapors (the fashionable neurosis of eighteenth-century ladies). He advised the husband to simulate the symptoms of his wife's illness. The husband did so, and the wife, who was very much in love with him, took so much care of him that she forgot her own ailments and recovered.

Many psychological problems were known and debated by Catholic priests. For a long time the only objective classifications and descriptions of sexual deviations were to be found in the treatises of moral theology. In Germany certain Protestant ministers practiced with success "Cure of Souls" (*Seelsorge*); they effected what amounted to a kind of brief psychotherapy by relieving the person of the burden of a pathogenic secret and helping to overcome the situation. In England the famous preacher John Wesley practiced medicine, opened dispensaries, and wrote a book, *Primitive Physics,* in order to give people a basic knowledge of medicine and hygiene; he was one of the first to use electricity as a therapeutic agent and had a profound understanding of many emotional problems. The Quakers included the insane among the unfortunates for whom they were concerned.

During the seventeenth and the eighteenth centuries the number of

mental institutions in Europe increased. They derived from two opposite models: the prison and the monastery. Institutions of the incarcerative type have been the subject of many descriptions. Who has not heard of the horrible conditions in Bicetre before Pinel conducted his reform? Michel Foucault contends that the modern philosophy of the mental institution was a product of the Age of Reason, that is, a reaction against "unreason": since the sight of the "fools" had become intolerable, they were hidden from the rest of mankind and incarcerated in large institutions together with the criminals, the cripples, and the beggars.

The other type of mental institutions derived from the monastery. Saint Vincent de Paul (1576-1660) founded institutions for delinquents where they received humane treatment. A glimpse of the treatment methods may be found in one episode of Abbe Prevost's novel, *Histoire de Manon Lescaut et du Chevalier des Grieux* (1731). As a punishment for his misbehavior, the Chevalier was committed to the Maison de Saint-Lazare in Paris; he was treated with firm kindness, isolation, silence, reading of serious books, and frequent conversations with tactful religious men. Actually we know very little about the results of this kind of therapy. But we are better informed about one of the institutions of the Order of the Hospitalers of Saint John of God, the Charite of Senlis, not far from Paris. The archives of that institution were preserved and utilized as the basis for an excellent monograph by Dr. Helene Bonnafous-Serieux. The inmates were classified into four groups: the

insenses (mental defectives), the *fous* (psychotics), the *libertins* (amendable behavior disorders, and the *scelerats* (dangerous psychopaths). According to their behavior the inmates were placed in one of three sections: the *force* (maximum security), the *semi-liberte* (medium security), the *liberte* (inmates enjoying certain privileges. The treatment was individualized. Emphasis was laid on the religious character of the institution, and inmates were invited to join the morning prayers and Mass. Every new inmate was given a pseudonym under which he was henceforth known; he had to wear a uniform that was more religious than prisonlike in character. The "director of the inmates" had a personal interview with each one of the inmates every day. There was a library, but no work therapy. There was no question of chains, whips, or cages and no demonology. Patients benefited from the medications known at that time and from a kind of rational psychotherapy. The registers show that many patients recovered, and it was reported that certain *libertins* improved their behavior.

We thus see that by the end of the eighteenth century there existed a small number of monastic institutions for a minority of privileged patients and a large number of incarcerative institutions where the poor lived in dreadful conditions. Meanwhile, a trend toward "sensitiveness" had appeared and a concern for the disadvantaged and rejected members of the great human family. An Englishman, John Howard, made a systematic inquiry into the state of the prisons all over Europe. Institutions were opened and

methods devised for the education of the blind, the deaf-mute, later of the idiots and feebleminded. Humane treatment was introduced in a few public mental hospitals, notably by Vincenzo Chiarugi in Florence, by Joseph Daquin in Savoie, and by Philippe Pinel (1745-1826) in Paris.

Few pioneers of psychiatry reached a fame comparable to Pinel's. However, recent historical research has shown that the current accounts of his life are covered with legend. For many years Pinel lived in Paris as a medical journalist and translator with a small medical practice, working upon a *Nosographie philosophique* in the style of Boissier de Sauvages. In 1793 he was appointed as physician to the medical wards of the hospital of Bicetre. The administration was in the hands of the "Governor" Pussin, an able man who was much concerned with the welfare of the patients and had already achieved several improvements. Pinel benefited from Pussin's experience and collaboration and gave his medical authority to the reforms. In 1795 Pinel was appointed to the Salpetriere hospital; he introduced the same reforms there, too. In 1801 he published his *Medico-Philosophical Treatise on Insanity,* expounding a clear and humane system for the care of mental patients. Contemporaries depict Pinel as a small, shy, unassuming, often absent-minded man with speech difficulties, but kind and good-humored. In later years a number of young physicians became his enthusiastic pupils. Pinel acquired the prestige of a hero: he had achieved his humane reforms in the notorious Bicetre (also a prison and house of arrest for vagabonds) during the

Terror, the worst period of the Revolution. Thus, he in his later years was a legendary figure, and after his death he became the patron saint of several generations of French alienists. Actually he had achieved a decisive step toward the foundation of a scientific and humane psychiatry.

Modern Scientific Psychiatry

With the nineteenth century began a new era of psychiatry. Within the framework of medicine—now a fully scientific discipline—psychiatry became an autonomous specialty (as were already surgery and ophthalmology). Attempts were made to give psychiatry a firm basis, either in brain anatomy or physiology, or even in a general "science of man" (one example was Cabanis's *Rapports du physique et du moral de I'homme* in 1802). Old Galenism and speculative systems were discarded, but new semiscientific systems based on a mixture of speculation and sound observation appeared on the periphery of psychiatry. Such were phrenology and mesmerism: their adherents elaborated fantastic speculations, but also made useful discoveries and contributed in their own way to the development of psychiatry.

The evolution of modern scientific psychiatry may be divided into three periods, which largely overlap each other:

> 1. From 1800 to 1860 the center of psychiatric activity was the mental hospital. Its main concern was the description and

classification of mental diseases, and the devising of a "moral therapy," together with the study of brain anatomy.

2. From 1860 to 1920 the center of psychiatric activity was the university psychiatric clinic. The trend was toward the elaboration of great psychiatric systems. A striking development occurred in the study of neuroses and culminated in the creation of schools of dynamic psychiatry.

3. After 1920 came a kind of psychiatric explosion, with an almost boundless widening of the field of psychiatry and its division into a multitude of subspecialties.

Asylum Psychiatry (1800-1860)

The main feature of the period of asylum psychiatry was the appearance of a new type of physician who devoted his whole time and activity to the mentally sick. These men sought to found, operate, and reform "asylums" satisfying the demands of science and humanity and open to all categories of mental patients. The old Charites institutions were sometimes taken as models, but the developments took different forms in various countries.

The main school of alienists flourished in France among a group of physicians who had been Pinel's pupils or proclaimed themselves his successors. Most prominent among them was Jean-Etienne Dominique Esquirol (1772-1840). "At the beginning of the continuous development of

psychiatry stands the outstanding personality of Esquirol," wrote Karl Jaspers. Esquirol devised a system of clear psychopathologieal concepts and gave their present definition to terms like illusion and hallucination, remission and intermission, dementia and idiocy. He inaugurated the use of asylum statistics for the study of the causes, course, and prognosis of mental disease. He proclaimed that "an insane asylum is a therapeutic instrument in the hands of an able physician, and our most powerful weapon against mental illness." He laid the foundation of a collective therapy, analyzing the influence exerted by the patients upon each other and grouping them accordingly. He wrote the first really scientific textbook on mental diseases, which was also the first to have illustrations, a book remarkable for its style and clear clinical descriptions. He became the director of the National Asylum of Charenton, which had been rebuilt according to his own plans on the site of a former Charite of the St. John of God Hospitalers. He visited every place where mental patients were kept in France, "house by house, hospital by hospital, prison by prison." These inquiries resulted in his magnificent illustrated treatise on the construction of asylums. Esquirol was also foremost in forensic psychiatry and the author of the French law on the insane (1838).

A young French physician, Laurent-Jesse Bayle, discovered in 1822 that "general paresis" was not a complication—as believed until then—but a specific mental disease with constant cerebral lesions. This encouraged the alienists eagerly to study cerebral pathology with the hope of discovering

new specific entities. Their efforts, however, brought fewer rewards than did the clinical observation of mental patients. Thus, Etienne Georget distinguished from idiocy and dementia a third condition, "stupidity" (transient, reversible impairment of intelligence). It was observed that mania and melancholia could succeed each other and alternate in such a way that they must constitute one identical condition. This discovery was published simultaneously by Jean-Pierre Falret and by Jules Baillarger in 1854. Ulysse Trelat gave fine descriptions of the *folie lucide* and Charles Lasegue of the delusions of persecution.

A new trend was open by Jacques-Joseph Moreau de Tours's book on hashish (1845), showing that this drug produced a state of delusions and hallucinations that—he believed —was for a few hours identical with the manifestations of insanity and afforded an experimental approach to its study. On this basis he came to consider the dream as the key to the knowledge of mental life, and the *desagregation* (in today's language, "regression") as the basic psychopathological process.

Benedict-Augustin Morel (1809-1873) published in 1852 a description of *demence precoce,* not as a disease entity, but as a peculiar form of rapid evolution of mental illness toward a state of severe emotional impairment (the term was later misunderstood to mean "dementia at an early age"). He also described phobias under the name of *delire emotif* (emotional delusions).

Morel inaugurated the psychiatric application of physical anthropology and genealogy. He photographed patients, measured their skulls, took plaster casts of their heads, investigated their lives and the lives of their parents and ancestors. This was the basis for his theory of degeneracy. Degeneracy, Morel said, was a gradual process; its manifestations became worse from one generation to the next, until the descendants were sterile, which automatically ended the process. But Morel also discussed the ways of checking the progress of degeneracy and making it reversible; in these studies were the beginnings of social anthropology and mental prophylaxis. Morel also introduced the psychiatric use of etherization, that is, studying a patient's reactions under the administration of ether as a means of diagnosing between hysteria and organic disease (as today with narcoanalysis).

In the meantime German psychiatry, starting from a very different background, had undergone its own evolution. It seems that the German asylum tradition issued more from the prison than the monastery, and this is, according to Kirchhof. the reason for their tremendous use of coercive measures. On the other hand, German psychiatry underwent the strong influence of Romanticism and of Schelling's philosophy of nature. Whereas French alienists based their nosology on the empirical study of clinical cases, their German colleagues often tried to isolate abstract types deduced from a psychological frame of reference. German psychiatry soon developed into two trends: the *Physiker* (organicists) and the *Psychiker* (who emphasized the

psychological origin and treatment of mental illness).

Among the *Physiker* were Johannes Friedreich, also known as one of the first historians of psychiatry, and Maximilian Jacobi, author of a treatise on the architecture of mental hospitals.

The *Psychiker* took over from Stahl the notion of the role of emotions in the etiology of mental illness. Each one of them developed his own views about the human mind and the nature of mental illness with great originality and audacity. Johann Christian Reil (1759-1813), though also a brain anatomist, expounded in his *Rhapsodien* (1803) an extraordinary program of psychotherapy for mental illness, including the use of a "therapeutic theater." Johann Gottfried Langermann (1768-1832) is considered a pioneer of occupational therapy. Johann Christian Heinroth (1773-1843) pointed out the role of "sin" (in modern language, guilt feelings) in psychopathology; he, too, devised an extensive program of psychotherapy for mental illness. Karl Wilhelm Ideler (1795-1860) emphasized the effects of frustrated sexual drives in the psychogenesis of mental diseases. Heinrich Wilhelm Neumann (1814-1884) devised an original system of medical psychology. He discussed the relationship between anxiety and frustrated drives, and he described the masked manifestations of sexuality among psychotic patients. All these men were skeptical in regard to the current psychiatric nosologies; they shared the belief in the emotional causation of mental illness and the possibility of

psychotherapy for even severe psychotics. They anticipated much of what Eugen Bleuler, C. G. Jung, and the psychoanalysts were to teach as great novelties several generations later.

One belated representative of German asylum psychiatry was Karl Ludwig Kahlbaum (1828-1899), who spent his career in remote asylums and whose publications were ignored for a long time. His main contribution to psychiatry was his descriptions of hebephrenia and catatonia (the former delegated to his collaborator, Ewald Hecker, in 1871; the latter in his own monograph, 1874). The validity of Kahlbaum's concepts was accepted later by Emil Kraepelin who made hebephrenia and catatonia two subforms of dementia praecox.

In Belgium Joseph Guislain taught that almost all mental diseases had emotional causes and were rooted in an all-pervading, underlying feeling of anxiety. In his institution in Ghent he organized an excellent system of work therapy. Wonderful accounts of moral therapy were also published by those who visited Pietro Pisani's institution in Palermo, Sicily.

In England William Tuke's pioneer work in the "Retreat" near York was pursued by descendants and their collaborators. One of the latter, M. Allen, founded his own institution at High Beach and wrote a highly instructive account of his therapeutic methods. To give only one instance: patients with

violent agitation, accompanied by an attendant, were sometimes allowed to ramble about and scream in a forest for a whole day, with a subsequent lessening of their agitation. Henry Maudsley (1835-1918) began his *Physiology and Pathology of the Mind* (1867) with a chapter about the unconscious and the impossibility of exploring the human mind through introspection. Maudsley advocated the use of a "physiological method" that would take into account the "plan of development" of the mind (in the animal, the infant), the study of its "degeneration" (in the dream, delirium, insanity), and of its "progress and regress" throughout history.

In the United States Benjamin Rush (1745-1813) introduced "moral treatment" at the Pennsylvania Hospital in Philadelphia. Other mental institutions operated along similar lines. Isaac Ray (1807-1881) founded American forensic psychiatry, and Thomas Kirkbride (1809-1883) is famous for his book on the construction of mental hospitals.

Throughout the period of asylum psychiatry, a noteworthy discrepancy is often found between the theoretical views of the alienists and the real state of their mental hospitals, as pictured by visitors. The term "moral treatment" was given many conflicting meanings. In France Francois Leuret (1797-1851) used to treat delusional patients with icy cold showers until they came to recognize their "errors"; he called that method "moral treatment."

Outside asylum psychiatry ran a kind of underground current centered around the use of "magnetic sleep," later called hypnosis. Mesmer, Puysegur, and a long succession of followers treated many neurotic and psychosomatic patients. They developed a full-fledged First Dynamic Psychiatry, which was later to give birth to the modern schools of dynamic psychiatry.

University Clinic Psychiatry (1860-1920)

The historical examples of Morel and Kahlbaum showed how difficult it was to achieve important creative work in a mental asylum. For that reason the center of scientific activity gradually moved to the psychiatric university clinic, a threefold institution for treatment, teaching, and research. For some reason German psychiatry outdistanced France around i860 (with the exception of the field of neuroses), but as time went on, psychiatry became more international.

A new type of psychiatrist arose, the university psychiatrist who worked with a team of collaborators and pupils and was provided with well-equipped laboratories. Techniques of brain anatomy were improved, new biological methods and experimental psychology were resorted to. The field of psychiatry expanded swiftly. Among the new clinical pictures were alcoholism, morphinism, cocainism, neurasthenia, and traumatic neuroses.

Wilhelm Griesinger (1817-1868) is usually considered the founder of

German university psychiatry. Possessing an eclectic mind, he introduced Herbart's psychological concepts into psychiatry, but his contention that "mental diseases are brain diseases" was taken as a slogan by the adherents of organicism. At that time Rokitansky and Virchow were laying the foundations of cellular anatomo-pathology, which appeared to be the one firm basis of all medicine. This encouraged psychiatrists to rebuild psychopathology on a similar basis. Theodor Meynert (1833-1892) supplemented his objective anatomical findings with hypotheses on the functional opposition between the brain cortex and brain stem and on the role of physiological brain disturbances. However, he was not so exclusively organicist as he is usually depicted; he pointed to the psychogenesis of homosexuality and other sexual deviations. Carl Wernicke (1848-1905) attempted a brilliant synthesis of brain anatomy, physiology of the nervous reflex bow, and associationist psychology. He considered the brain an associative organ and the soul as being "the sum of all possible associations." Only the most elementary mental functions are localized in the cortex, he said; the higher ones, including consciousness, are products of the associative activity. Unfortunately these men and many of their colleagues fell into "brain mythology," the tendency to explain all mental phenomena in terms of real or fictitious brain structures.

The credit for overcoming "brain mythology" as well as the current nosological confusion belongs to Emil Kraepelin (1856-1926). An eclectic

researcher, Kraepelin combined neuroanatomical research with experimental psychology and a thorough investigation of the patients' life history. In the sixth edition of his textbook (1899) he defined the two great endogenous psychoses: manic-depressive psychosis (the old "circular illness") and dementia praecox. The latter comprised three subforms: hebephrenia, catatonia, and paranoia. Contemporaries felt that Kraepelin had shed definitive light on the chaos of psychiatric nosology. His classification was widely adopted in Europe and America.

In Zurich Auguste Forel (1848-1931) started with discoveries in brain anatomy but shifted toward a dynamic concept of the mind. Among his pupils were Eugen Bleuler and Adolf Meyer. Eugen Bleuler (1857-1930) sought a deeper psychological understanding of psychotic patients; he revolutionized the concept of dementia praecox, which he called schizophrenia. He introduced many new terms such as autism, ambivalence, and schizoidism.

In France Valentin Magnan (1835-1916) extended the theory of mental degeneracy so widely that this diagnosis covered almost the whole realm of psychiatry. His fame, however, was the result of his clinical studies on alcoholism. But the main French contribution to psychiatry was the work of a neurologist, Jean-Martin Charcot (1825-1893), and of an internist, Hippolyte Bemheim (1840-1919). These two men gave the official stamp of approval to the use of hypnosis, thus making it a respectable procedure, though their

theoretical concepts and therapeutic use of the phenomenon differed widely. A large part of the teaching of the old magnetists and hypnotists was rediscovered. From about 1880 to 1900 hypnotism and suggestion were widely investigated and utilized.

In England probably the most original contribution to psychiatry was made by a neurologist, Hughlings Jackson (1834-1911). He conceived of man's neurological and mental structure as a hierarchy of functions, resulting from differentiation and perfection through evolution. Nervous and mental disorders were explained by "dissolution" (regression) to inferior, older levels of functions. In such disorders Jackson distinguished negative symptoms resulting from the loss of a higher function and positive ones resulting from the activation of functions of a lower level. Jackson's theory had a great impact on many neurologists and psychiatrists.

In the United States George Beard (1839-1882) described "neurasthenia," a state of physical and mental exhaustion, as a neurosis of modern, and especially American, life. Beard's ideas met with great success. S. Weir Mitchell (1829-1914) devised a standard method for the treatment of neurasthenia by means of rest, isolation, feeding, and massage. After the turn of the century the main American contribution to psychiatry came from Adolf Meyer (1866-1950). In his individualized, psychobiological approach, Meyer interpreted mental disorders as being faulty reactions to life situations, which

he tried to understand with the help of a thorough study of the patient's life history and development.

Gradually several branches of psychiatry expanded and tended to become sciences in their own right. Thus, the field of sexual pathology had been explored by forensic psychiatrists. Now a brilliant systematization was effected by Richard von Krafft-Ebing (1840-1902). His *Psychopathia Sexualis* (1886) was the starting point of the flourishing new discipline of sexology. Another forensic psychiatrist, Cesare Lombroso (1836-1909) founded a school of criminal anthropology in Italy. He conceived of it as being a branch of biological medicine, but when sociologists and lawyers joined his group the newer criminology became an autonomous science.

We have seen that Charcot and Bernheim had incorporated into medicine a part of the teachings of the First Dynamic Psychiatry. Their attempts, however, were short-lived. The first man who undertook to build a new dynamic psychiatry was Pierre Janet (1859-1947). Janet was able to correlate hysterical symptoms with "subconscious fixed ideas" and bring a cure by means of a "psychological analysis." He then elaborated a new theory of the neuroses, of mental energy, of the "hierarchy of tendencies," and eventually a vast conceptual model that illuminates in some way virtually every phenomenon of the mind. But whereas Janet had kept closely within the bounds of traditional psychiatry, Freud and the founders of the newer

dynamic schools openly broke with official medicine.

The work of Sigmund Freud (1856-1939) is so widely known that it is hardly necessary to recall its main features. Among his theories are those of the dynamic unconscious and the deciphering of symptoms, the interpretation of dreams, repression and other defense mechanisms, the development, fixations, and regressions of libido, child sexuality, the superego, the Oedipus complex, the sexual origin of neuroses. Freud introduced a new approach to the unconscious by means of free associations, and analysis of resistance and transference: he developed a new approach to therapy by means of a development and resolution of a transference neurosis. From the beginning Freud made of psychoanalysis a movement, then an organization of a new type that had no parallel in modern times, that is, a close, tightly structured organization with its official doctrine and rules for membership, including a long initiation in the form of a didactic analysis. Gradually psychoanalysts extended their interpretations to sociology, anthropology, literature, art, religion, education, and all manifestations of cultural life. Some of its adherents had the feeling that the history of psychiatry was now divided in two periods: before and after Freud.

Psychoanalysis was the starting point of a vast development of dynamic psychiatry. Among Freud's disciples were orthodox and deviant groups. Both Alfred Adler (1870-1937) and Carl Gustav Jung (1875-1961) developed a

system that was basically different from psychoanalysis. Adler's individual psychology is a pragmatic or concrete system centered around the dialectic of the individual's striving for superiority versus his community feeling. Jung's analytic psychology centers around the concepts of the collective unconscious, with the archetypes, and the process of individuation.

The new dynamic psychiatric systems grew outside the realm of "official" medicine. Their theories extended far beyond the traditional limits of psychiatry. This was a manifestation of a new trend that could be called the "psychiatric explosion."

The Psychiatric Explosion (1920—)

After World War I it became obvious that the psychiatric university clinic could no longer remain the only center of psychiatric progress. Kraepelin founded in Munich the first *Forschungsamtalt* (psychiatric research institute). It was discovered that considerable impetus could be given to scientific progress if specialists could be liberated from daily treatment and administrative work and devote their whole time to carefully planned research projects. Similar institutes were founded in Germany, Russia, America, and later in other countries.

From that time on, the field of psychiatry continually expanded. Former branches became autonomous disciplines (for instance, child psychiatry,

sexual psychopathology, clinical criminology), and new branches were founded. Among the latter were genetics (Rüdin, Luxemburger), biotypology (Pende, Kretschmer, Sheldon), reflexology (Pavlov) electroencephalography (Berger), psychiatric endocrinology (Manfred Bleuler), intelligence testing (Binet and Simon, Terman), projective testing (Rorschach, Murray, Szondi), organo-dynamic psychiatry (Henri Ey), general psychopathology (Jaspers), phenomenology (Minkowski), existential analysis (Binswanger). There also was a great development in social psychology, transcultural psychiatry, family psychiatry, psychosomatic medicine, and a variety of approaches to community psychiatry.

Among the new therapeutic methods we may mention perfected forms of ergotherapy (Herman Simon), malaria therapy (Wagner von Jauregg), narcotherapy (Klaesi), narcoanalysis (Horsley), cardiazol therapy (Meduna), insulin shock therapy (Sakel), electric shock therapy (Cerletti), psychosurgery (Egas Moniz), and last but not least, the pharmacotherapy of mental diseases (Laborit and many others). In psychotherapy a great variety of new methods were introduced, in addition to the adaptation of psychoanalysis to the treatment of children and psychotics. We may mention Rogers's nondirective therapy, Frankl's existence therapy, Schultz's autogenous training, and various methods of behavior therapy. Not less numerous are the varieties of group therapy, therapeutic communities, and psychodrama.

The description of all these clinical and therapeutic developments will be an absorbing and arduous task for psychiatric historians of the future.

Meantime, the traditional principles that had ruled psychiatry for a long time were shaken. Henri Ey had warned that the boundless expansion of psychiatry—which he called "panpsychiatry"—would inevitably lead to a reaction in the form of the dissolution of psychiatry. This is exactly what present-day psychiatry is witnessing. A number of "antipsychiatrists" now proclaim that mental illness does not exist; what is called by that name is nothing but the artificial product of social repression; psychiatric treatment is nothing but a disguised form of punishment, of social violence; a sojourn in a mental hospital can never cure a patient but only make his condition worse; mental hospitals should be closed and psychiatrists take up another profession. As Henri Ey had predicted, "panpsychiatry" has led to "antipsychiatry."

Thus, the outcome of 25 centuries of efforts is that the basic principles of psychiatry are in need of careful revision. This is not unique to psychiatry and reminds one of what Bachelard once wrote: "All scientific knowledge must be, at every moment, reconstructed. ... In the work of science only, one can love that which one destroys; one can continue the past while denying it; one can honour one's master while contradicting him."

Chapter 2

American Psychiatry From Its Beginnings To World War II

Nolan D.C. Lewis

Psychiatry has developed in combination and association with the other branches of medicine to the extent that its borders, as a specialty, in certain areas are not sharply outlined, and, moreover, most of its particular concepts and aims are exceedingly difficult to trace accurately in terms of their chronological appearance.

Medicine is seen within a matrix of economic, political, social, and cultural elements. It is but one aspect of the state of general civilization of a period, and its particular philosophy and practice are determined to a considerable extent by the current cultural conditions of its locality and time.

To attempt to trace the complex growth of psychiatric thought is an interesting experience. The most satisfactory way to understand a complicated phenomenon is to follow its pathway of genesis, but to cover the

span of time indicated by the title of this chapter, one must resort to a condensed style of communication. The topic includes more than a hundred years, during the early parts of which are revealed only a few records of basic importance in our particular field; however, there are some outstanding persons and events that appear as bright promises of progress to come in later years.

Since the aim in this chapter is to indicate some of the most important trends of thought that constitute the background of present-day psychiatry in this country, no attempt has been made to present a complete history of psychiatry in America, and thus many workers and their accomplishments have been omitted. In psychiatry as well as in other branches of medicine, one can find pioneers, men whose energy and curiosity were so great as to lead them to devote their lives to the promotion and extension of knowledge beyond the existing outposts of what was accepted and practiced. Benjamin Rush (1745-1813), "America's first psychiatrist," was one of these men.

At the termination of the American Revolution in 1783, Dr. Benjamin Rush joined the staff of physicians at the Pennsylvania Hospital in Philadelphia, which event is often referred to as being the actual beginning of American psychiatry. Although at this time Rush was only 38 years old, he was already a very famous physician. He had been a precocious student, having graduated from the New Jersey College (now Princeton) at the age of

He received his doctor's degree from the University of Edinburgh at the age of 22. While at Edinburgh he studied under William Cullen (1710-1790), who was one of the most famous professors of medicine of his time, with an interest in the nervous system and in behavior phenomena. Cullen was a follower of Locke, but he originated a new doctrine of physiological significance. In his system irritability of the nervous system was of special importance, and the causes of mental disorders were within the individual, that is, endogenous. Insanity was a pathological condition of the mind and not some force entering from without, and, therefore, its expressions should be interpreted in the light of normal psychological functions. His *First Lines of the Practice of Physik* (London, 1777) described paranoid forms of mental disorder that he called "vesaniae." Rush was introduced to Cullen by a letter from Benjamin Franklin, a fortunate occurrence since Cullen exerted a strong influence on Rush's subsequent career, which was thus oriented in the theory and therapy then prevalent in Scotland and England.

Dr. Rush, equipped with a keen mind and the best training available at the time, attacked the problems of mental disorder, a subject that was infiltrated with superstition and ignorance as well as characterized by neglect and actual brutality. He was apparently the first American physician to approach the investigation and treatment of mental disorders from a scientific viewpoint, the first American teacher to propose an original systematization of psychiatry, and the first to write a general treatise on

psychiatry in America. This book, published in 1812 under the title *Medical Inquiries and Observations upon Diseases of the Mind,* remained the only American book of its kind for 70 years.[1]

Rush's principal remedies were purgatives, emetics, and bloodletting, of which he was a particularly strong advocate. The condition of the blood circulation in the brain was a prominent focus for his theories and therapy. He devised two curious instruments, the gyrator, based on the principle of centrifugal action to increase cerebral circulation, and the tranquilizer (1810) "to obviate these evils of the 'strait waistcoat' and at the same time to obtain all the benefit of coercion." These instruments, which were certainly rough on the patient, were decidedly "shock" measures—a form of shock therapy, and, like all shock therapies including the modem ones, were interpreted as effecting cures.

Benjamin Rush was one of the earliest, if not the first, to recommend labor and prison sentences instead of capital punishment for criminal offenses, and he consistently advocated a modification of the harsh and cruel elements in the system of criminal jurisprudence. In the minds of many medical historians, he did for America what Pinel and Esquirol did for France. His biographers are in accord that he, like many originators and creators, was a strongly opinionated man, difficult to get along with, frankly intolerant of anyone who did not agree with his theories and practices, and at times

actively quarrelsome. He was a very learned man who not only served the poor of his community but also was a leading patriot and a signer of the Declaration of Independence. His was an overwhelming personality, fully justifying the title by which he is known today, "The Father of American Psychiatry."

Dr. Adolf Meyer (1866-1950) in 1945 made the following pertinent comment:

> Had Benjamin Rush had a successor akin to his own spirit American psychiatry may have had the lead over the European and its actually colonial development. It took a hundred years before the step towards a culture for responsible life began to assert itself. ... I do not know what the names and teachings of the immediate successors were. . . . Psychiatry may see the influence of the 1840's in J. P. Gray.[28]

Psychiatry has always been more hospital-centered in England and other countries than it has here in America, but there were some important early, as well as later, developments of this nature that are of historical significance. For example, the old San Hipolito, established in Mexico in 1566 by the philanthropist Bernardo Alvares, was the first hospital in the Americas for the study and care of mental disorders and, of course, one of the earliest for this purpose in the whole world. At first this institution was not devoted exclusively to the treatment of mentally disordered patients, but before long the increase in the number of these cases made it necessary to restrict the admissions to nervous and mental patients.

It was nearly 200 years before the first institution to care for the mentally disordered in the American states was organized. In 1752 the Pennsylvania Hospital in Philadelphia received insane patients, and this was followed by a few other public and private institutions. In 1773 the first public hospital exclusively for mental patients was established at Williamsburg, Virginia, then the capital of the colony. For half a century mental patients were kept at the Pennsylvania Hospital in cells in different parts of the building, but in 1796 a new wing was provided for these patients, and at the end of another 50 years a separate building was constructed for them. The Blooming- dale Asylum was another of the early institutions for the mentally disordered. It was opened in the New York City area in 1821 as a separately managed hospital, although it had its beginnings in the earlier founding of the New York Hospital. It continues today in White Plains, New York, as the Westchester Division of the New York Hospital.

Out of a meeting held in 1844 by a group called the "original thirteen" came the organization known as the Association of Medical Superintendents of American Institutions, which was the first national society of physicians in the country. From 1893 to 1921 it was known as the American Medico-psychological Association, and is now the American Psychiatric Association, with a large and ever growing membership. In the year of its origin (1844) the *American Journal of Insanity,* later to become *The American Journal of Psychiatry,* the official organ of the Association, was established under the

editorship of Amariah Brigham (1798-1849), one of the original thirteen superintendents. The *Journal* has continued to be a leader in the field by virtue of the management of a line of distinguished editors.

In their day the "original thirteen" made a lot of psychiatric history, both as a group and as individuals. It is well to note some of their particular contributions as pioneer workers.

Samuel B. Woodward (1787-1850) was the first president of the Association of Medical Superintendents of America and a strong force in its organization. He aided in establishing the Retreat for the Insane at Hartford, Connecticut. In 1832 Massachusetts was the first state in New England to build a state hospital. Woodward supervised the construction of this hospital and became its first superintendent. He believed in specialized medical care for alcoholics, and in 1838 his volume entitled *Essays on Asylums for Inebriates* was published. He was elected to the Connecticut state legislature in 1830.

Isaac Ray (1807-1881) was an avid student of scientific matters, both in America and in Europe, and a prolific writer. He was one of the most eminent and versatile of the group. In 1841 he became medical superintendent of the State Hospital for the Insane at Augusta, Maine, and later of the famous Butler Hospital in Providence, Rhode Island. He wrote a book on mental hygiene in

1863 and was interested particularly in the relationship between legislation and mental disease. As a matter of fact, the first book in the English language concerning forensic psychiatry was published by Ray in 1838; this book made a profound impression and established him as a pioneer and leader in medicolegal matters. The title of this book was *Treatise on the Medical Jurisprudence of Insanity.* It was used as an authoritative text for court work for nearly 50 years.

Amariah Brigham (1798-1849), founder of the *American Journal of Insanity,* was a distinguished author, teacher, and hospital administrator whose influence for the better understanding and care of the mentally sick was widespread. He wrote lucidly on such diverse subjects as cholera, religion, clinical neurology, and clinical psychiatry. At one time he taught anatomy at the College of Physicians and Surgeons in New York City. In 1842 he was appointed superintendent of the State Lunatic Asylum at Utica, New York, the first New York State public institution for the mentally disordered. This hospital, under his inspiration and effort, became an outstanding training center for medical superintendents. His book entitled *Remarks on the Influence of Mental Cultivation upon Health* had a remarkably wide American and European distribution.

Pliny Earle (1809-1892), in 1844, was appointed superintendent of the Bloomingdale Asylum in New York. In 1863 he became professor of

psychological medicine at the Berkshire Medical Institution in Pittsfield, Massachusetts. This may have been the first chair of psychiatry in a medical school in this country, and it was certainly one of the very early additions of psychiatry to a medical curriculum in the United States. From 1864 to 1885 he was superintendent of the State Lunatic Hospital at Northampton, Massachusetts.

Dr. Earle was an able hospital administrator and an outstanding contributor to the literature on mental disease. He was well versed in the European psychiatry of the day, introducing new ideas from Germany and France. He published many statistical papers, psychiatric reviews, and historical essays, and lectured widely. In 1877 he published a statistical treatise entitled *The Curability of Insanity.* He had a critical mind and a far-reaching vision, recommending small hospitals for intensive treatment and separate ones for the incurable patients. He was also an early advocate of family care and occupational therapy.

Thomas S. Kirkbride (1809-1883), after receiving his medical degree from the University of Pennsylvania in 1832, became resident physician at Friends Asylum, followed by a residency at the Pennsylvania Hospital, and later by the appointment as superintendent of the new Pennsylvania Hospital, a position that he held for 43 years during which time he was a progressive advocate of many reforms in the care and therapy of mental patients and

served as an active participant in community affairs.

Dr. Kirkbride published many important books and articles. In 1847 he published an article on hospital construction that made such an impression that for at least 50 years the "Kirkbride type" of hospital building was adopted by many institutions. A notable number, if not most, of the "Kirkbride type" buildings are still in active use today in the older mental hospitals. Dr. Earl Bond[4] has written a most informative book, *Dr. Kirkbride and His Mental Hospital,* about this remarkable personality and his achievements.

William M. Awl (1799-1876), after some years in general practice, settled in Columbus, Ohio, in 1833, where he became active in the organization of a mental hospital, the Ohio State Asylum for the Insane. He became its first superintendent in 1838 and remained at this post for 12 years, when he was removed by political factions. He then returned to private practice and also became physician at the Ohio Institute for the Blind.

Although Dr. Awl possessed keen mental abilities, he wrote very little on mental disorders. He devoted much time and thought to the organization of the state asylum and the institute for the blind, and was concerned with the organization of the Ohio Medical Society.

Luther V. Bell (1806-1862) became superintendent of the McLean Asylum in Somerville, Massachusetts, when it had been in operation for 19

years. He received his medical degree from Dartmouth at the early age of 20, was in general practice for a time in New Hampshire, and also served in the state legislature, as well as participating in establishing the State Asylum at Concord before taking the post at McLean Asylum.

Dr. Bell wrote on a wide range of medical subjects, including an original description of a form of acute mania, which was named after him (Bells disease). During his active professional lifetime he received many awards and honors and was a participant in a variety of local and national civic activities. He was the only one of the "original thirteen" to have served in the Civil War, during which he died, in 1862, in an army camp near Washington, D. C., where he was a medical inspector.

John S. Butler (1803-1890), after receiving his medical degree from the Jefferson Medical College in Philadelphia in 1828, entered private practice in Worcester, Massachusetts, until 1839, when he was appointed superintendent of the Boston Lunatic Hospital. Here he soon instituted various reforms and striking improvements in the hospital treatment of patients. In 1843 Dr. Butler was electcd superintendent of the Bctreat for the Insane at Hartford, Connecticut, to succeed Dr. Amariah Brigham, who had gone to Utica, New York. Dr. Butler remained at the Betreat for nearly 30 years, during which time he demonstrated outstanding leadership and a progressive spirit. He remained active in medical matters for another ten

years after retirement from hospital service.

Nehemiah Cutter (1787-1859) received his medical degree from Yale University in 1817 and entered private practice in Peppcrell, Massachusetts, where he gradually built up a specialty of treating the mentally ill to the point of organizing a private hospital known as the Peppcrell Private Asylum. This hospital was successful despite the prejudice extant against private mental institutions. The hospital burned down in 1853 and was not rebuilt; however, Dr. Cutter continued his successful career as a practicing physician.

Charles H. Stedman (1805-1866) graduated from the Harvard Medical School in 1828, and in 1830 was appointed resident surgeon at the United States Marine Hospital at Chelsea, Massachusetts, where he worked for ten years. In 1834, being keenly interested in the theories of Gall and Spurzheim, he edited a translation of Spurzheim's book on brain anatomy. Dr. Stedman started a private practice in Boston in 1840, and two years later he became superintendent of the Boston Lunatic Hospital, following the resignation of Dr. Butler. Here he proved to be an exceptionally able administrator and student of mental disorders. He was also particularly active as a staff member and consultant in medicine and surgery in various other hospitals in the city.

Samuel White (1777-1845) opened an office for private practice at Hudson, New York, in 1797 at the age of 20. He apparently never attended a

medical school but gained his professional education by means of the apprentice system, which was possible in those early times. In 1830 he opened a private hospital, called Hudson Lunatic Asylum, where he functioned successfully until his death. From the historical fragments that have been recorded about his life and ideas, one may assume that he was progressive in thought, was accepted as an authority by his contemporaries, and that he utilized the best methods known in practice.

Francis T. Stribling (1810-1874) obtained his medical degree from the University of Pennsylvania in 1830. He was in private practice for a time in Staunton, Virginia, his native town, and at the age of 26 was appointed physician to the Western Lunatic Asylum of Virginia. Dr. Stribling left very little published work, but he was an able clinician and was one of the early advocates of training for attendants, of prompt treatment for acute cases, and of occupational therapy.

John M. Galt (1819-1862) was a young man of 22 when he received his medical degree from the University of Pennsylvania in 1841, and in this year he was made the first superintendent of the Williamsburg Asylum, which had been established many years before ([1]773)- He was an unusually erudite man who read many languages and was thus able to bring important psychiatric literature to the attention of American physicians. In 1846 he published a book entitled *The Treatment of Insanity,* which contained a summary of about

all of what was known of mental disorders. Other books and many articles came from his pen, and, although his life span was comparatively short, his was a powerful influence for progress since he advocated the proper keeping of records, the performance of autopsies, the value of research, and the need for changes in the legal aspects of psychiatry. He utilized in his hospital several of the adjunct therapies that are in vogue today.

Of these founders of the Association of Medical Superintendents of American Institutions for the Insane, six were in charge of state institutions, five directed incorporated hospitals, and two were the proprietors of private hospitals. From the intelligence of this remarkable group of men and the examples they set in their respective areas have developed many of our modem attitudes and endeavors in the specialty. At the time they formed their national association, European psychiatry, although still relatively young as a medical discipline, had progressed to a point where the mentally sick were no longer treated as monsters or criminals but as patients suffering from very serious disorders.

Another important powerful force in the evolution of American psychiatry, for many years after 1841, was Dorothea Lynde Dix (1802-1887) Boston. This remarkable woman, a retired schoolteacher, became "shocked" by how she saw mental patients cared for in certain places, where they were locked up in filthy cells and were not only neglected but often treated brutally

as well. Through her widespread activities not only in the United States but also in Canada, the British Isles, and on the European continent, reforms were instituted successfully through various government agencies. She is credited with having been directly responsible for creating or extending the facilities of a total of 32 hospitals. In this country 20 states built or enlarged mental hospitals as a result of her personal efforts. The Government Hospital for the Insane (now St. Elizabeths Hospital) in Washington, D.C., is among those that she aided in establishing.

On the second day of the second annual meeting of the American Neurological Association held at the College of Physicians and Surgeons in New York City in 1876, with 16 members present. Dr. George M. Beard (1839-1883) presented a paper entitled "The Influence of Mind in the Causation and Cure of Disease and the Potency of Definite Expectation." This paper was remarkable in its originality as it dealt clearly with what is now known as psychosomatic medicine. Such a presentation was new and startling, in fact so startling that the famous neurologist, Dr. William A. Hammond, remarked during the discussion that if the doctrine advanced by Beard was to be accepted, he "should feel like throwing his diploma away and joining the theologians."

According to the original report in the *Transactions of the Association,* "Dr. Beard maintained that disease might appear and disappear without the

influence of any other agency than some land of emotion. Mental qualities, like drugs, could neutralize therapeutics and they could also increase the effect of drugs. Fear, terror, anxiety and care, grief, anger, wonder and expectation were regarded as the most likely to produce disease." To the criticisms referring to mental therapeutics as being nothing new, Beard replied that he had not implied that psychotherapy was new, but that it had not been carried out in a systematic manner by the profession. Although there was much vigorous critical discussion and skepticism, the brilliant Beard, pioneer in the field, defended his position with confidence and ability. When Beard's famous paper entitled "Neurasthenia (Nervous Exhaustion) and Morbid Fears as a Sympton of Nervous Disease" appeared (1869), his term "neurasthenia" was gradually adopted over the whole world as "Beard's disease," and he was duly recognized as a great pathfinder.

Among the prominent American alienists of the 1880s were Allan McClane Hamilton, Walter Channing, John Chapin, John P. Gray, W. A. Hammond, and E. C. Spitzka. Dr. Hammond, usually considered as a neurologist, also taught psychiatry and wrote a book, *Insanity in Its Medical Relations,* that came into active use as a text. Dr. Spitzka, in 1883, published the *Manual of Insanity,* which included about all that was known and taught of the subject. Although the term "paranoia" (which means "mental disorder" in the original Greek) was introduced into medicine by Vogel in 1764 after which it had rather widespread applications, it was Dr. Spitzka of New York

who, out of a welter of conditions and names, differentiated it as a specific disorder. It is therefore an American-named psychosis, as we use and understand the term today.

One of the strongest influences to bear upon American psychiatry was the work of Emil Kraepelin (1856-1926). He was professor of psychiatry successively at Dorpat, Heidelberg, and Munich and is generally considered to have been the greatest of all descriptive psychiatrists whose concepts increased and enriched the whole field. He was a systematizer who, following periods of active analysis of data, attempted a synthesis of scattered facts and ideas. Kraepelin had a large amount of clinical and laboratory material with which to work, and he made his studies according to the natural history method, in that he followed the course of mental disorder in the individual cases from the earliest symptoms on through to the termination. By means of this method it became possible for him to make a new grouping of mental disorders on which some basis for prognosis, therapy, and prevention could be ascertained. He was after the causes, the course, and the outcome of mental disorders with reference to any pathological lesions and processes, and he was interested in any mental trends and clinical pictures that tended to terminate in various degrees of deterioration.

In 1883 Kraepelin published the first edition of his *Psychiatrie,* which subsequently passed through several revisions and translations into other

languages. The English translation of the book changed the whole aspect of classification of mental disorders in America. His outstanding contributions to the description and delineations of dementia praecox states and manic-depressive conditions have held a central position in psychiatric thought and practice from the time they were first introduced to the present day. His clinical descriptions of the psychoses can still be read with a great deal of profit by the student of psychiatry.

The concept of dementia praecox was later elaborated and expanded into schizophrenia by Eugen Bleuler (1857-1939) in 1911. Among this eminent Burgholzli professor's numerous original contributions that have vitalized psychiatry in all civilized areas are the psychology of dementia praecox (schizophrenia), including the phenomena of ambivalence and of autistic thinking, and the delineation of the schizoid and syntonic personalities, and some later biophilosophical theories.

About one year after the birth of Kraepelin, a man was bom who was not only to revolutionize psychiatry but to influence the philosophic thought of the whole world, namely Sigmund Freud (1856-1939). After a period of interest in neurology, Freud went to Paris to study under Charcot, who was the outstanding clinical neurologist of his day, and who had developed a system of hypnosis for the treatment of hysteria. After returning home to Vienna, Freud carried out some studies of his own, and in 1895 the *Studien*

ueber Hysterie was published, followed by the *Traumdeutung* in 1900. These studies represented a new approach to the investigation of human motivation and to the phenomena of the unconscious. Freud had replaced hypnosis with his method of free thought association and dream interpretation.

Freud's technique made it possible, for the first time, for a physician to devote his time to attempting to understand the innermost working of the patient's mind rather than directing the patient's life in matters that were obscure to everyone involved. For a number of years Freud worked alone, but later, when he was well on his way to success despite the great amount of opposition from critical contemporaries, students of the mind began to take an interest in the concepts, and a number of now well-known names appear in the list of his special pupils, supporters, and co-workers. Among these are Karl Abraham, Sandor Fer- enczi, Carl Jung, Alfred Adler, Wilhelm Stekel, Otto Rank, Hans Sachs, Paul Federn, and Ernest Jones.

Jung, Adler, Rank, and Stekel later developed some special modifications of psychoanalysis contrary to Freud's wishes. He insisted that these modifications were not really psychoanalytic and were of such a nature that they necessitated his breaking off professional relationship with these workers. However, these doctrines all found followers in America and elsewhere, as have the later modifications of some of Freud's theories and techniques such as those of Sandor Rado, Franz Alexander, Karen Horney, and

Harry Stack Sullivan among others in this country.

In 1909 Freud made a personal appearance in America to lecture under the auspices of Clark University in Worcester, Massachusetts. It may be said that practically everything that Freud wrote has at one time or another been translated into the English language, but in those earlier years America became rather thoroughly acquainted with the Freudian literature through the efforts of Abraham A. Brill, who first translated Freud's works, and of Smith Ely Jelliffe and William A. White, both of whom were outstanding leaders in psychiatric thought and freely disseminated such knowledge through their prolific writings of books and articles. Psychoanalysis soon gained a wide acceptance and became gradually incorporated into psychiatric thought and procedure.

Psychoanalytic teaching and practice were organized and standardized by the establishment of psychoanalytic institutes and societies directed and supported by highly trained specialists in several large cities in America as well as abroad. The psychoanalytic literature that has accrued over the years reveals a considerable diversity of trends, but in the main they fall into two general categories—(1) that which includes investigations aimed at extending the field of metapsychology, where the unconscious structure of the superego, the material gained by hypnosis, and the pregenital infantile frustrations are the principal topics, and (2) that which attempts to adapt

current theories to clinical confirmation. There are now an ever increasing number of able workers interested in testing the validity of the libido theory and other concepts pertaining to various psychiatric conditions, in understanding the physiological manifestations of mental attitudes by means of combined studies in cooperation with modem biological laboratory disciplines, and in establishing an interpretation of neurotic symptoms in terms of somato- biological activity.

A group of Fellows of the American Psychiatric Association formed a Section in Psychoanalysis within the Association in 1933, and a year later a symposium was given in this section on the relation of psychoanalysis to psychiatry, which marked the beginning of a new era in the history of psychoanalysis in America. The conclusions were to the effect that the psychoanalytic formulations of Freud were established as indispensable to the procedures of treatment and research, and that requirements of technique, the investigation of unclear or incomplete knowledge, and the application of therapeutic procedures to selected clinical groups were being continually studied and that it was to be expected that modifications of psychoanalytic conceptions would take place to a considerable extent.

Another prominent psychiatric development took place under the leadership of Adolf Meyer (1866-1950). He came to America from Switzerland as a young man, well trained in neuroanatomy, neuropathology,

psychiatry, and philosophy. Following services as a pathologist in the state hospitals of Kankakee, Illinois, and Worcester, Massachusetts, he became director of the New York State Psychiatric Institute on Wards Island where, as early as 1906, he was working on his concept of integration with the total individual as a unit. From the beginning he emphasized the pathological evolution of the symptoms of psychiatric disorders in terms of all of the presenting facts. His was a dynamic system.

Later in 1912 Dr. Meyer becamc director of the Henry Phipps Psychiatric Clinic and Professor of Psychiatry at the Johns Hopkins Medical School. He formulated through the subsequent years the reaction type of behavior and his concepts of social adjustment. He created a fresh, unique attitude toward the individual as a totality and brought the term "psychobiology" into the foreground. By training many psychiatric teachers in this discipline, he created a school of thought— particularly the concept of psychobiology— that has had a notable influence on psychiatric developments, particularly in this country and Great Britain.

Early in the 1900s Elmer E. Southard (1876-1920), another great ferment in psychiatry, developed the psychopathic hospital idea and also brought into the foreground the training of social workers in psychiatry. Adolf Meyer had brought social work into psychiatry as early as 1904, but in 1912 it was Southard who expressed clearly the social aspects of psychiatry and

extended its interests into the training of social workers and into industrial hygiene. His famous book *The Kingdom of Evils,* with Mary C. Jarrett as co-author, was published in 1922 after Southard's death. This book dealt with social case work, presenting 100 case histories together with a classification of social divisions of evil. In 1919 he said, "Social psychiatry is far from the whole of mental hygiene, for mental hygiene includes also the far more difficult and intriguing topic of the individual as related to himself and his organ processes." Here is reflected the keen interest he always had in the organic reactions of the body and brain, which were the principal foci of his original researches.

It seems that the term "mental hygiene," in its generally accepted meaning, first appeared in the literature in 1843 in a book entitled *Mental Hygiene or an Examination of the Intellect and Passions Designed to Illustrate Their Influence on Health and Duration of Life* by Dr. W. C. Sweetser, Professor of Therapy and Practice of Physic at the University of Vermont. Dr. Isaac Ray also wrote a book ten years later entitled *Mental Hygiene.* He defined it as the art of preserving the health of the mind, and he emphasized that all methods of preserving mental health came under it. However, many years were to pass before the mental hygiene movement became a force for psychiatric progress. In 1908 Clifford Beers published his book, *The Mind That Found Itself,* which created a tremendous interest. By his efforts, together with those of

Adolf Meyer and others, the National Committee for Mental Hygiene was organized in 1908. Dr. Meyer suggested the name "mental hygiene" for this committee, which has now been renamed the National Committee for Mental Health. It began with twelve charter members, among whom were three prominent psychiatrists, August Hoch, Adolf Meyer, and Frederick Peterson; the famous psychologist, William James; and the Johns Hopkins internist, Lewellys Barker. In 1912 Dr. Thomas W. Salmon (1876-1927) was appointed director.

The chief aims of the Committee were clearly stated: (1) to work for the protection of the mental health of the public; (2) to strive to raise the standard of care for the mentally ill and for those in danger of becoming mentally disordered; (3) to promote the study of all types of mental illness and to disseminate information concerning their causes, therapy, and prevention; (4) to obtain from every available source reliable data regarding methods of dealing with mental disorders; (5) to enlist the help of the federal government to the extent desirable; and (6) to coordinate the existing agencies and to aid in the organization, in each state, of an allied but independent society for mental hygiene.

The dynamic concepts of Freud, Pierre Janet (1859-1947), and Adolf Meyer strongly emphasized psychotherapy. The early workers in America as well as elsewhere had considered psychotherapy in terms of moral treatment,

occupational therapy, recreational activities, and similar procedures, but the followers of the exponents of dynamics, such as A. A. Brill, S. E. Jelliffe, and W. A. White, among others, basing their teachings on the concept that mental symptoms are the expressions or symbols of meanings that are obscure and hidden in the unconscious, made a widespread impact on psychotherapeutic practice, which proceeded along the lines of what could be learned from a study of what was going on in the deeper recesses of the patient's mind.

Under the influence of some of Janet's ideas and formulations, but contributing a number of concepts of his own, was the Boston psychiatrist Dr. Morton Prince (1854-1929) of Tufts Medical School. He worked with what he termed "co-conscious phenomena," adding much to the knowledge of hysteria, multiple personalities, and hallucinations. He never fully accepted the significance of the unconscious in the Freudian sense of its meaning, and he disagreed with Freud's theory of the libido. He founded the *Journal of Abnormal Psychology.* His famous case of a girl with multiple personality was studied for over seven years and published in 1908 under the title *Dissociation of a Personality;* it is probably the most complete report ever made of this phenomenon. Another interesting contribution to the literature was his *Experimental Study of Visions.* He applied psychotherapy within the framework of his personal concepts.

Trigant Burrow (1875-1951), originally a Freudian, organized his own

special group of students in what he termed "phyloanalytie" investigations of human behavior and social adjustment. He stressed the defensive distortions of man's natural reactions through the dominance of visual-verbal part functions resulting in internal tensional disorders called neuroses. He developed a system of psychotherapy aimed at the reduction of these tensions.

Paul Schilder (1886-1940), coming to America after having had a distinguished career in Vienna, contributed to the knowledge of several areas of the psychiatric and neurologic fields. His concepts of integration and his development of the body-image significance in various mental states are among the subjects with which he enriched the literature. The work of Harry Stack Sullivan (1892-1949) and his associates systematically developed the theme of interpersonal relationships, which Freud had taken into consideration but did not develop or emphasize in the same way. The basis of some of Sullivan's conclusions stemmed from the assumption that parataxic illusions arc derived from earlier anxiety experiences. To Karen Homey and Sullivan neuroses were products of cultural environment and distorted interpersonal relationships rather than based on the preformed instincts, as Freud thought. Sullivan organized and published the journal called *Psychiatry*, which still serves as a useful medium for psychiatric thought.

In the field of therapy as well as those of pathology and diagnosis, a

significant event was the obtaining in pure culture of the *Treponema pallidum* in 1911 by Hideyo Noguchi (1876-1928), and in 1913 Joseph W. Moore (1879-1957), of New York. Noguchi demonstrated the spirochete in the brain tissue of patients dying of general paresis, thus proving that this mental disorder was precipitated by a form of syphilis. Following this laboratory demonstration, general paretics were treated by the arsenicals and other drugs used for syphilitic disorders, but without marked success. In 1918 Julius Wagner von Jauregg (1857-1940) of Vienna announced his now well-known malarial therapy for general paresis. This treatment, strikingly successful as compared to other known procedures, promptly came into general use, and the first to apply it in America was the staff of the St. Elizabeths Hospital in Washington, D.C., from which the first paper in English on the results of this treatment was published, as far as I am informed.[25]

During World War I psychiatry was brought more prominently into the foreground and received a long-neglected consideration among the other medical specialties. At the beginning of the war the government called upon the National Committee for Mental Hygiene for aid, and this organization was exceedingly fortunate to obtain and recommend the services of Dr. Thomas W. Salmon (1876- 1927), who had a remarkable organizing ability. Through his efforts it was demonstrated that psychiatry could contribute a great deal to the efficiency of the armed services by recognizing and treating the war neuroses. Salmon and his associates in the Army, with its numerous civilian

as well as military personnel problems, were instrumental in pointing out the relationship of these problems to medical and social disciplines. By extraordinary patience and hard work, Salmon overcame seemingly insurmountable obstacles and problems. He had confidence in the future of psychiatry and was always alert to defend it against any unfair criticism. He profoundly influenced the growth and course of psychiatry in America, and it may be pointed out that what he did for the Army has stood the test of time, as his methods are still more or less in force and, in the minds of some, are still the best available, having been so proved in World War II and in the Korean campaign.

One of the most significant and practically important phases of the mental hygiene movement to the credit of American psychiatry was the creation of child guidance clinics, which started with William Healy (1869) in 1909 in the institute devoted to the study of juvenile problems in Chicago. This was the pioneer child guidance clinic, although the term was not coined until 1922. The Boston Psychopathic Hospital, opening in 1912, accepted children from the first, as did the Phipps Psychiatric Clinic in Baltimore where a special outpatient children's clinic was activc as early as 1913. The Allentown State Hospital in Pennsylvania was also a pioneer in this field, with a clinic under way in 1915. Child guidance clinics developed rapidly in other cities and areas under such well-known specialists as Lawson Lowrey (1890-1957), David Levy (1892), Frederick Allen (1890-1969), J. S. Plant (1890-

1946), and Douglas Thom (1887-1954) and are continuing to grow in size and distribution, as the needs for the study and correction of the behavior disorders of childhood are still greater than the available facilities.

Researches of many types have been carried on from early times, particularly on nervous system anatomy and functions, but intensive organized research, as such, on mental disorders is of comparatively recent development. For example, in 1884 Dr. I. W. Blackburn of Philadelphia, an excellently trained pathologist with a particular interest in the relationship between the brain and mental diseases, was appointed special pathologist at the Government Hospital for the Insane (now St. Elizabeths Hospital). He was the first fulltime pathologist in a mental institution in America (at least I can find no record of an earlier full-time appointment of this kind). He published 25 papers and books during a period of 25 years, many of them illustrated by his own hand, since he was a skilled artist as well as a scientist.

Probably the first large-scale stride toward organized systematic psychiatric research in this country was made in 1895 by the establishment of the Pathological Institute of the New York State Hospitals as an integral part of the state hospital system. Located at first in New York City with Dr. Ira van Gieson (1865-1913), a neuropathologist, as director, this institute was later constructed on the grounds of the Manhattan State Hospital on Ward's Island where it remained for many years under the successive directorships

of Adolf Meyer, August Hoch (1868-1919), and George Kirby (1875-1935). In 1929 the old institute was replaced by a modern building constructed as a unit in the Columbia Presbyterian Medical Center and named the New York State Psychiatric Institute and Hospital. During the past 60 years this institute has been unique since it has been supported for the sole purpose of research.

The Boston Psychopathic Hospital built in 1912 under the direction of Elmer Southard (1876-1920), the State Psychopathic Hospital under Dr. Albert M. Barrett (1871-1936) constructed in 1906, and later the Colorado Psychopathic Hospital under Franklin Ebaugh (1895-1972) are among the earliest centers with active research units employing full-time research workers. With these beginnings acting as stimuli, there have been many similar developments in university and hospital centers. Moreover, the philanthropic foundations have devoted large sums of money to train young research workers in the psychiatric field, to support investigators already in key positions, and to finance laboratories where original studies could be carried out. In 1934 the Scottish Rite Masons of the Northern Masonic Jurisdiction began their support of research projects in schizophrenia, which has continued to the present day with accomplishments that have served as an example of the progress that may be expected with the growth of research interests and financial aid.

The work of Sir Charles Sherrington (1857- 1952) of England on the

physiology of the nervous system and of Walter Cannon (1871- 1945) of America on the relationship between the emotions and the vegetative nervous system, as well as the investigations of the followers of Pavlov's (1849-1936) concepts and to a lesser extent those of Kretschmer (1888-1971) on bodily conformation, have served as a background upon which the structure of "psychosomatic" or "comprehensive" or "total" medicine has been erected and expanded in recent years. The term "psychosomatic medicine" has been known for at least 100 years, but in the sense of the modem clinical application and theories in psychopathology and medical problems it is rather distinctly an American development to which Adolf Meyer and Smith Ely Jelliffe contributed a great deal.

Here it is well to remember that George Beard of New York described a syndrome in 1868 that he called "neurasthenia" and under which he included pathological fatigues and so-called nervous exhaustion. He said, "While modern nervousness is not peculiar to America, yet there are special expressions of nervousness that are found here only: and the relative quantity of nervousness and of nervous diseases that spring out of nervousness are far greater here than in any other nation in history and it has a special quality." These disorders, regardless of whether there were more of them in America than elsewhere, were the disorders to which Silas Weir Mitchell (1829- 1914) of Philadelphia devoted much thought and therapy. He ascribed them to deficiencies in fat, blood, and other elements and

recommended complete rest as the cure. From the general interest in so-called functional disorders came one of the special roots now known as psychosomatic medicine.

Forensic psychiatry, as such, has developed slowly in America through the years despite the fact that there have been outstanding pioneers with constructive concepts and writings. Beginning with Isaac Ray's book in 1838, one finds interesting and pertinent references to the relationship between psychiatry and the law and recommendations for dealing with these complicated problems. In more recent years the publications and personal influence of such authorities as L. Vernon Briggs (1863- 1942), William A. White (1870-1937), Bernard Glueck (1884-1973), Winfred Overholser (1892-1964), and Gregory Zilboorg (1890-1958) have made excellent contributions to the subject in ways that have favorably modified some of the practical legal procedures.

Since World War I industrial psychiatry, school and college psychiatry, and other penetrations of psychiatry into public affairs have made notable strides that have led to a deeper understanding of emotional phenomena. Clinical psychology, occupational therapy, and social service activities, all of which are valuable psychiatric auxiliaries, have shown remarkable progress. In the field of clinical psychology the use of the Rorschach and other projective techniques became established and were freely applied to

psychiatric problems. The social worker, from the first, proved to be practically indispensable in investigating the home situation, in the problems of hospital patients and of the child guidance field, and in interpreting the nature of the problem to the family as well as aiding in the readjustment of the improved patient in the community.

Occupational therapy, in the broad sense of its original definition ("any activity, mental or physical, definitely prescribed and guided to hasten recovery from disease or injury"), has always accompanied enlightened, humanitarian treatment, especially in the field of mental illness. It may have begun in the United States with the opening of the Pennsylvania Hospital in 1752, when the board of managers provided wool-carding and spinning equipment "to employ such Persons as may be capable of using the same." Activities ranging from music, games, and arts and crafts to industrial or housekeeping tasks and education were utilized as an essential feature of the nineteenth- century "moral treatment" as mental hospitals opened in Philadelphia, New York, and Boston. Nursing personnel frequently supervised these activities, though no formal preparation for such leadership was available until Susan

Tracy established a course for student nurses at Adams Nervine Hospital. By 1917, when the Society for the Promotion of Occupational Therapy (later the American Occupational Therapy Association) was formed,

two more training centers were functioning. Three other schools, originated during World War I to train "reconstruction aides" for Army hospitals, continued to grow and were among those accredited in 1938 by the American Medical Association. Graduate therapists, like their predecessors, worked in various hospitals and rehabilitation centers, using a wide range of activities to promote patients' recovery from physical as well as mental illness.

As late as the 1930s it was advocated by many that psychiatry was not a science but an art, since the personality of the psychiatrist bulks so large in the practice of mental medicine, and psychiatry could never free itself from its philosophic elements. Regardless of what was thought and said, an "American school" was developing, and by 1937 it had the following characteristics, most of which have persisted.

The American school had started to use the new shock therapies that later became so widespread in application, and it had also recognized the great possibilities of sociology and cultural anthropology as contributors to psychiatric knowledge. However, this American movement was not merely a composite eclecticism, but it was beginning a positive frontal attack upon the problems of mental medicine that was new, frank, and critical. It advocated treating all behavior, thought, and feeling of an individual as real or actual performance or, in other words, as a personality experience. The differentiation of human performances and capacities is just as much a real

dynamic phenomenon as is any feature of somatobio- logical processes or of social culture. It also emphasized proceeding along the following general lines in dealing with a particular psychiatric problem: (1) the correction of all recognized defects in the soma of the patient; (2) the establishment of adequate rapport between physician and patient; (3) the careful study and evaluation of familial, economic, and social situations; (4) the detailed investigation of the personality problem; (5) the attitude toward and adjustment to reality; (6) the ventilation of conflicts and desensitization of the patient; (7) the institution of re-educational training; (8) the formation of an adequate philosophy of life; and (9) the desirability of follow-up studies.

The American school recognized, and attempted with considerable success to correct, the lack of adequate instruction and training in psychiatry in many of the medical schools; in fact, in most of the medical centers psychiatry was inadequately represented. However, despite these educational handicaps, a greater number of medical students sought postgraduate training, and the number of women physicians entering psychiatry became notably larger since earlier strong prejudices against them had subsided considerably. It is a matter of interest to note that in 1890 a law was passed by the New York State legislature authorizing the appointment of at least one woman physician in each state hospital. Obviously we have come a long way during the last half century. The lack of sufficient knowledge of mental hygiene and the psychic components of disease on the part of the general

practitioners and the lack of proper psychiatric information among the clergy and the population in general were also well recognized, and movements were started to try to correct these deficiencies.

In recent years, and particularly since World War II, more adequate methods and techniques suitable for attacking vital problems have appeared and are still in various stages of evolution. In scrutinizing the past in an attempt to perceive the simple beginnings and origins of the present-day science of man, one should remember that each worker, regardless of his individuality, is in some degree dependent on the thought and practice of his time, uses to some extent formulations suggested by others, and is stimulated and influenced by the particular interests of his friends and colleagues.

Notes

[1] Benjamin Rush is also claimed by professional chemists as the "Father of American Chemistry" on the basis that he was the first professor of chemistry in America, his post being the College of Philadelphia (1769-1789).

Chapter 3

Recent Psychiatric Developments (since 1939)

George Mora

Introduction: General and Methodological Issues

A succinct presentation of the development of psychiatry in the last three decades is not an easy task, especially in view of the great deal of progress made in this field since the end of World War II, of the difficulties involved in carrying on meaningful research in this area, and of the lack of adequate historical perspective to evaluate properly the events related to this progress.

The fact remains, however, that in the period under consideration psychiatry has gained acceptance in the overall realm of medicine and, even more, in the American culture by and large. Psychiatry has now reached the point of being able to look comfortably at its present situation and to draw from the past inspiration for the future.

In this country, following Albert Deutsch's *The Mentally Ill in America* and Gregory Zilboorg's A *History of Medical Psychology*, a number of general histories of psychiatry, biographical studies (mainly the thorough, yet biased, study on Freud by E. Jones), histories of diseases, of institutional care, and of basic concepts and trends related to psychiatry (such as the important volume on the development of the unconscious by H. Ellenberger) have appeared.

Moreover, the emphasis on newly published primary sources—for example, Freud's correspondence with pupils and admirers—and on the historical dimension of sociological attitudes toward the mentally ill has become significant. Even the American Psychiatric Association, which has taken many initiatives through its Committee on History, recognized the importance of its own development by republishing the presidential addresses of the last quarter-century on the occasion of the 125th anniversary of its foundation in 1969. In the introduction to this publication, as well as elsewhere, I myself have discussed many important points related to the history of psychiatry, to which the interested reader is referred.

The historical dimension, when presented from a broad cultural perspective, can help to predict future developments and to introduce optimism into the study of certain phenomena—such as apparent manifestations of collective psychopathology and widespread use of "drugs of

the mind"—that find antecedents in similar episodes in the past.

Because of space limitations only topics relevant to the main areas of psychiatry have been considered here. Events related to special and collateral fields of psychiatry, included in the first edition of this *Handbook,* have been omitted. Also, in discussing specific points, full source information has not been provided in the text or in the bibliography, as this will be done in the following chapters of this work.

National Recognition of Psychiatry

Shortly after the first edition of this *Handbook* was published in 1959, *Action for Mental Health,* a milestone in American psychiatry, appeared. The main psychiatric events that took place in the 25 years from the end of World War II to then can be seen as progressively leading to the realization of such an important document.

American psychiatry had originated from the British and continental impetus toward moral treatment in the first part of the nineteenth century, followed by the emphasis on institutionalization of a large number of mentally ill in isolated settings in the second part of the century. The emphasis on the organic etiology of mental disorders has been slowly superseded by Meyer's psychobiology, a convergence of the new European psychodynamic theories and the optimistic American view of environmental

forces.

In the late thirties early attempts were made to improve the treatment of hospitalized patients through the development of aftercare programs in the community, better administrative policies in state institutions, and better training of personnel at every level. The introduction of shock therapies around that time helped to focus attention once again on psychotic patients and on organic psychopathology and research in general; in the two previous decades, at the beginning of the child guidance movement, attention had shifted to neurotic and antisocial patients.

The child guidance movement, originating from the desire to prevent juvenile delinquency, had eventually based its platform on a combination of individual psychodynamics and environmental behaviorism. By the third decade of this century research on new ideas—child psychiatry, criminology, alcoholism— advanced and new clinical techniques, such as projective tests, were introduced. Under the influence of the many psychoanalysts who emigrated from Europe to this country as at the beginning of the forties to escape the Nazi persecution of the Jews, new impetus was given to individual psychotherapy in its various modalities and, to a lesser extent, to research in the new areas of psychosomatic medicine and experimental neuroses.

By that time World War II had revealed the magnitude of psychiatric

problems: syndromes of acute breakdown in relation to combat, a large number of inductees rejected for psychiatric reasons, and rehabilitation of many veterans suffering from psychiatric disorders. In a short time the problem of mental illness came to be recognized at a national level. Especially urgent was the need to train a great number of professionals and nonprofessionals, far above the few psychiatrists hitherto trained with the assistance of some private organizations, such as the Rockefeller Foundation and the Commonwealth Fund.

The Vocational Rehabilitation Act (1942), the National Mental Health Act (1946) leading to the creation of the National Institute of Mental Health (1949)—for research, training, and assistance in developing mental health programs—the National Governors' Conference on Mental Health, the establishment of separate departments of mental hygiene on mental health in many states, these and many other developments can be seen as steps along a continuum of increasing national concern about mental illness.

In 1955 the Mental Health Study Act was passed, providing for the creation of the Joint Commission on Mental Illness and Health. This commission, composed of outstanding leaders from many organizations, in five years of intensive work produced the above- mentioned *Action for Mental Health,* essentially geared to shift the emphasis from institutional to community care of the mentally ill. Eventually in 1963 under President

Kennedy the Community Mental Health Act was passed, providing for the creation of a network of community mental health centers able to offer a comprehensive program of prevention, treatment, and rehabilitation throughout the entire nation. Finally in 1965 funds for staffing these centers were allocated through an amendment to the act.

Regardless of the effectiveness of these legislative actions, they point unequivocally to the recognition of the problem of mental illness at a national level and to a concerted effort to deal with it.

Research and Methodology

In this country research was first carried on systematically at the Pathological Institute (now New York Psychiatric Institute) founded in 1896, and at the Henry Phipps Psychiatric Clinic of Johns Hopkins University inaugurated in 1919 by Adolf Meyer. Early research projects tended to focus on histopathology, genetics, endocrinology, and neurophysiology; later on the themes of juvenile delinquency, psychosomatic disorders, and emotional deprivations became prominent.

Research in psychiatry is vitiated by certain methodological drawbacks related to the difficulties in measuring psychological phenomena, in reaching agreement on symptoms and diagnoses, in producing animal experimentation meaningful for human beings, especially by interdisciplinary teams composed

of scientists having different ideas and biases. Moreover, most of the research tends to be supported by the federal government, which relies on a relatively small number of experts, who are inclined to favor certain projects and themes. Efforts by the government to encourage young psychiatrists to carry on research through mental health careers, investigation careers, and career development awards have met with limited success.

In addition, psychiatrists arrive at the end of their training in their thirties, when the process of creativity is already in decline; in the course of their training they do not receive adequate preparation in research methodology. Consequently research designs tend to be carried on by psychologists, more interested in proper methodology than in creativity, and often in themes peripheral to the mainstream of psychiatry. It is a fact that most of the "discoveries" in psychiatry—from psychoanalysis to shock treatment, psychopharmacology, and community innovations—have been made mostly in Europe by individual psychiatrists often working in poorly equipped settings. The typical pattern has been for American research teams to thoroughly investigate and critically assess discoveries achieved somewhere else through a variety of methodology including double-blind designs, use of placebo, selection of cohorts of patients for comparative purposes, follow-up of patients, "research alliance" between researcher and patient, and so forth.

Twenty years ago Lawrence Kubie, an outstanding American psychiatrist, wrote that "research in psychiatry is starving to death." Since then a considerable amount of research has been carried on. Recently, however, the issue of research has become more complex than ever as the result of the upsurge of community psychiatry, which requires a difficult type of multidisciplinary research, involving clinical, statistical, and sociological dimensions and not immune from ethical and political pressures. The fear of losing the uniqueness of the doctor-patient relationship, so close to the core of psychiatry, has been voiced by some.

Classification: Normality and Mental Disorders, Epidemiology Statistics

Pathology is meaningful only vis-a-vis normality. Yet normality has not been the focus of psychiatric research up until the last decade or so; possibly the new attention on normality is a response to the need of assessing large groups of people in the context of the new community mental health movement. Among the recent pertinent publications mention should be made of *Current Concepts of Positive Mental Health* (edited by M. Jahova), which emphasizes individual self- actualization; *Normality and Pathology in Childhood* (by A. Freud), which is based on the psychoanalytic developmental perspective; and *Normality: Theoretical Concepts of Mental Health* (by D. Offer and M. Sabshin), which is based on the four dimensions of health, utopia, average, and process. In very recent years the pseudoissue of a

"supernormality," that is, "expansion of consciousness" achieved with the help of certain drugs, has been brought forward. Although most psychiatrists reject this notion as absurd, it has a relationship with centuries-old techniques of mastering the body through the mind—from Yoga to Zen—used in the Far Eastern cultures.

Regardless of all this, in psychiatry, like medicine, the urge to classify reflects the fundamental antithesis of looking for what is different while, at the same time, trying to find what is common. Some years ago H. Ellenberger pointed to the biases of psychiatric nosology in terms of the nature and kind of classifications, the concept of nature, the projection of intellectual schemata, and the unconscious position of the researcher. Yet the history of psychiatry coincides with the history of psychiatric classifications. Since the beginning of our century Kraepelin's notion of the rigid pattern of mental diseases has been superseded by Freud's developmental views and, in this country, by A. Meyer's emphasis on mental diseases as "reaction types"—a position that was accepted in the 1952 official classification of the American Psychiatric Association.

Since then many psychiatrists have stressed the increasingly "dull" aspects of psychiatric symptoms, up to the point of simple boredom or "alienation"; others have emphasized the trend from a cross-sectional to a longitudinal dimension and from "outer" behavior to "inner" feeling; the

poorly differentiated "borderline syndrome" (thoroughly described by R. Grinker) and "social breakdown syndrome" (E. Gruenberg) have been described; and finally mental illness has been considered as a "myth" supported by the psychiatric establishment (T. Szasz).

In the light of all this the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-II) published by the American Psychiatric Association in 1968 seems a rather conservative document, attempting to fit into the general scheme of the eighth edition of the International Classification of Diseases (ICD-8), published by the World Health Organization in 1966. At this point it is uncertain what future awaits bold new attempts (such as *New Approaches to Personality Classification,* edited by A. Mahrer) to base classification systems on new parameters (for example, having the patient himself participate in his own evaluation).

Rather, in the light of the community mental health movement, the importance of carrying on research on epidemiology has become evident. Following the methodological clarification of the notions of "incidence rate," "prevalence rate," and "system analysis," epidemiological studies have focused on the incidence of mental disorders in a certain area in toto (Hollingshead and Redlich in New Haven, Rennie, Srole, and collaborators in Manhattan, the Leighton's group in Stirling County, Dohrenwend, in the Washington Heights district of New York City), or in regard to hospitalized

mental patients (Malz- berg in New York, Dayton in Massachusetts), to particular ethnic groups (Eaton and Weil on the Hutterite), to samples of brain damaged and retarded children (Pasamanick, *et al.,* in Baltimore).

The impetus toward epidemiological research—in this country by E. Gruenberg and others under the sponsorship of the Milbank Foundation—has resulted in the establishment of psychiatric registers (for example, in Rochester, N.Y., by the Tri-County in Raleigh, N.C., and by the National Clearing House of the NIMH in Bethesda, Md.). Computers, first introduced at the Institute of Living in Hartford, Conn., in 1962, have later been used in other places (New York State Department of Mental Hygiene, New York State Psychiatric Institute, Department of Computer Science of the Stanford University Medical Center in Palo Alto, Calif., Missouri Institute of Psychiatry in St. Louis, the Beiss- Davis Child Study Center in Los Angeles, and a few others). The statistical refinement brought about by the use of computers is outweighed in the minds of some by their dehumanizing aspect, which runs counter to the very essencc of psychiatry. As a senior psychiatrist, Carl Binger, has put it, if the computer takes over, the psychiatric role may be "reduced to machine-processed data of being pushed around like pawns on a chessboard of science.

Psychopathology

Biological Research

America's original contribution to psychiatry can be traced back to Cannon's concepts of homeostasis and of the autonomous reactions of the organism under stress in the midtwenties, influenced by the dynamic theory of personality and by behaviorism. Such a typical expression of American melioristic philosophy of life was challenged by the great depression in the thirties and by the spread of psychoanalytic ideas in the forties.

The biological trend in psychiatry, which had been prominent in the late nineteenth century, gained momentum again at the end of World War II, for example, the founding of the Society of Biological Psychiatry. Among the main research themes were: stress reactions in Air Force servicemen (R. Grinker and J. Spiegel), theory of emotions (J. Papez), visceral brain (P. MacLean), reticular system (G. Moruzzi and H. Magoun), theory of cell assembly (D. Hebb), stimulation of cerebral cortex (W. Penfield), functions of the frontal lobes (J. Fulton), "stress syndrome" and "general adaptation syndrome" (H. Selye), theory of bodily defensive reaction (H. G. Wolff), experimental neuroses (J. Masserman), and psychosomatic conditions (F. Alexander and collaborators at the Chicago Psychoanalytic Institute).

The tendency of psychiatric research in the forties, under the influence of the psychoanalytic movement, to rely more on personal intuition than on scientific methodology, was superseded by the discoveries in

psychopharmacology in the fifties, which represented a return to the philosophy of biological psychiatry. Of the many topics mention should be made here at least of: the genetic role of the DNA molecule and the transmission of coded messages through the RNA; conditioning responses leading to behavior forms of therapy; clinical recognition of positive spike phenomena in EEG and of REM signs in sleep and dreaming; clinical aspects of sensory deprivation of psychominetic agents, of drug tolerance and abuse; functions of lymbic and reticular systems, of the temporal lobe, and of the neurotransmitters in psychiatric syndromes and in relation to chemotherapy; finally inborn errors of metabolism, enzymatic defects, and chromosexual abnormalities (Down's, Turner's, and Klinefelter's syndromes), leading to new investigating techniques (sex chromation determination, amniocentesis, cytogenetic study of criminal individuals) and to concern for family planning based on genetic counseling.

Such research, mainly carried on by teams of experts from the fields of neuroanatomy, neurochemistry, electrophysiology, and heredity, is largely supported by the National Institute of Mental Health, the National Institute of Child and Human Development, and the National Science Foundation. Even if one disregards Freud's prediction that the ultimate cause of mental disorders will be found one day in biological processes, the fact remains that nowadays a comprehensive view of the personality has to take into consideration the importance of biological research. The collaborative volume *Psychiatry as a*

Behavioral Science (published under the auspices of the Committee on Science and Public Policy of the National Academy of Science and the Problems and Policy Committee of the Social Science Research Council) represents an excellent survey of this field.

Anxiety and Related States

Anxiety is intrinsically related to the human condition of longing for eternity but having to accept death: a theme that can be traced from St. Augustine and Pascal to Kierkegaard and the contemporary existentialists.

In psychiatry the role of anxiety became paramount in Freud's various formulations; his final conceptualization of anxiety as a signal of danger from within (1926) led to the notions of defense mechanisms and of ego psychology. In addition to the semantic difficulty of differentiating between the philosophical and the psychopathologieal meaning of the term, anxiety has been seen as both "positive" (that is, facilitating purposeful behavior) and "negative" (that is, interfering with such behavior) from time to time.

In this country from the forties on, many studies have been devoted to "separation anxiety"; Hans Selye has described the above- mentioned "stress syndrome" and "general adaptation syndrome" as a global reaction of the organism resulting from the interplay of two opposite endocrinological constellations; S. Wolf and H. Wolff have differentiated fear from anxiety on

the basis of experimental studies on gastric secretion; others (D. Funkenstein) have differentiated unexpressed anger (anger-in) from expressed anger (anger- out) on the basis of the mechanism of action of epinephrine and norepinephrine; still others have studied anxiety in experimentally induced neuroses.

These studies have been criticized on various grounds, such as the difficulty of translating animal into human behavior. From a more clinical perspective Sandor Rado has attempted to explain the notion of emergency behavior as related to the level of organization of emotional and unemotional thought; and cultural anthropologists, followed by the neo- Freudians, have insisted on the importance of societal factors in the causation of anxiety, which from a defense may turn into a symptom (K. Horney). Finally the advent of psychopharmacology in the mid-fifties has brought the focus back on the symptomatic factors of anxiety regardless of the total personality. No matter what perspective one adheres to, anxiety remains a highly complex subject, as shown in the two monographs recently published by S. Lesse and by W. Fischer.

Unconscious, Dreams, Sexuality

The existence and main characteristics of the unconscious appeared to be established beyond doubt when the first edition of this *Handbook* was

published a decade ago. Freud's overwhelming emphasis on the unconscious, based on solid data on hypnosis, dreams, and countertransference, and its acceptance in psychiatric circles signified the final outcome of a long tradition beginning with the Greeks, running through the Romantics in the early nineteenth century, and leading to study of hypnosis by the French schools in the latter part of that century.

Although from the forties on the importance of the unconscious came to be reduced, with the emphasis on defense mechanisms and ego psychology, 110 one questioned its existence. As a matter of fact, fresh research on dreams, sensory deprivation, and posthypnotic phenomena seemed to add new evidence to the classical notion of the unconscious.

Yet in the last decade or so the advocates of the unconscious have found themselves on the defensive. Supporters of the new "behavior therapy" and of other related approaches question, not the validity of the notion of the unconscious, but its relevanec for psychiatric treatment, which they view as solely based on learning theory and on conditioning. Whether such a threat to the notion of the unconscious represents a temporary fad or will signify a persistent trend remains to be seen.

It is well known that dreams, like the unconscious, have a centuries-old tradition that can be traced back to ancient Middle East cultures, the Greeks,

and the Middle Ages. Such a tradition was given scientific form for the first time in Freud's *Interpretation of Dreams* (1899), which, by introducing a new methodology in psychiatry, initiated the "royal road" to psychoanalysis.

For several decades the importance of dreams was not questioned, although different emphases were placed on their interpretation at variance with Freud's insistence on their sexual and aggressive aspccts: compensation for social inferiority feelings (Adler); manifestation of collective unconscious and archetypal images (Jung); expression of ego's thrust for synthesis (Hartman and Kris); attempt to unify past and future in the light of ego identity and of a life plan (Erikson); struggle to achieve personal self-awareness and responsibility (neo-Freudians); finally a mode of personal existence (existentialists).

In recent years a revolutionary event has taken place: a new methodology based on the discovery of regular periods of eye motility during sleep (E. Aserinsky and N. Kleitman) and their relation to EEG patterns and content of dreams (C. Fisher, W. Dement, M. Ullman, F. Snyder, and others). An imposing amount of data has been gathered on the relation between rapid eye movements (REMPs) and nonrapid eye movements (N- REM), instinctual versus teleological role of sleep, clinical importance of "dream deprivation," interplay of neocortex and basal centers, new meaning of enuresis, somnambulism, nightmares, and so forth.

Interestingly enough this experimental research proves the erroneousness of some of Freud's basic tenets (such as dreams as protecting sleep and the connection between dreaming and psychotic states), while at the same time it points to the important role of interpersonal relationships, cultural aspects, and historically bound factors in the understanding of dreams. As a result, dreams are seen today from the threefold perspective of their neurobiological substratum, of their psychotherapeutic value, and of their relation to the preconscious level of artistic creativity. The recently established Association for the Psychophysiological Study of Sleep (APSS) is especially concerned with the first of these three aspects. Many interesting points are discussed in the literature of the last two decades, such as Fromm's *Forgotten Language,* Boss's *The Analysis of Dreams,* Tauber and Green's *Pre-logical Experience,* Bonime's *The Clinical Use of Dreams*, French and Fromm's *Dream Interpretation,* and Hall and Van de Castle's *The Content Analysis of Dreams.*

Expressions of sexuality easily can be traced back to every culture, from the early times on, in the literary as well as in the figurative fields. This is true even during periods of severe sexual repression, such as in the Middle Ages, when sex aberrations were expressed in the context of the witchcraft mania.

Early in our century Freud and his disciples faced the manyfold psychological aspects of sexuality in a candid way through the use of a new

verbal technique. Thus for the first time the centuries-old intuitions concerning the relationship of sexuality to psychopathology were given systematic form in terms of individual development. Freud's rather rigid model of the progression from the oral to the anal to the genital stage has remained valid to our day, though modified by some: for example, Alexander has attributed the sexual urge of adults to the surplus of energy after growth is completed at adolescence, while the neo-Freudians have stressed the cultural components of the sexual instinct.

Under the influence of the Freudian school the development of sexuality came to be studied directly in children, rather than in retrospect in adults, from the comprehensive perspective of anatomy, heredity, endocrinology, ethology, and sociology, and research was conducted also in non-Western cultures to test the universality of the psychoanalytic postulates. Eventually even the validity of a notion as basic as that of the oedipal complex came to be questioned.

Undoubtedly a more liberal view of sexual expressions has become noticeable concomitantly to the increasing acceptance of psychiatry. Without dealing with the issue of cause-and-effeet relationship between these two phenomena, mention should be made here of: the two Kinsey reports on the sexual behavior of the male (1949) and of the female indicating a wide range of sexual activity in the American culture; the bold methodological approach

introduced by R. Masters and V. Johnson in the psychiatric treatment of sexual disorders; the slowly gaining view of considering homosexuality from the psychological rather than from the moral perspective; finally the rapid reassessment of the role of the female vis-a-vis that of the male in this country as well as in other Western nations.

Formal or Structural Mechanisms, Cognitive Functions, the Intrapsychic Self

The various concepts listed in the heading of this section have come to acquire significance as the result of revisions of traditional Freudian notions and of the new fruitful integration of data acquired from psychoanalysis, developmental psychology, and other fields. It is the special merit of Silvano Arieti to have focused on the neglected area of the cognitive aspects of the personality in a series of publications that span more than two decades. According to Arieti, this new orientation has the following background: the pioneering eighteenth-century writings on prelogical thinking by the Italian philosopher Giambattista Vico; the differentiation between "abstract attitude" and "concrete attitude" in brain-damaged and schizophrenic patients (K. Goldstein); the essence of identity in paleological thinking being based on identical predicates rather than on identical subjects as in mature reasoning (Von Domarus); and finally the various models of the genetic development of the mind presented by H. Werner in *Comparative Psychology of Mental Development* and by J. Piaget in his many monographs.

In the past some attempts had been made to establish a relationship between psychotic symptoms and formal mechanisms of dreams, languages, and other human expressions (for example, by the Swiss A. Storch). However, traditionally the emphasis has been on the study of the content rather than the form of psychopathology. As Arieti put it: "The study of formal mechanisms reveals *how* we think and feel. The study of dynamics of psychoanalytic mechanisms reveals *what* we think and feel and the motivation of our thinking and feeling. Both the formal and the dynamic approaches are necessary if we want to understand psychological phenomena fully."

In his early writings, mainly in his *Interpretation of Schizophrenia* Arieti has described in detail the mechanisms of dreams, verbal associations, and infantile and paleological thinking. Later on he has tried to overcome the shortcomings of Freud's positivistic model of the mind and the culturalistic model of the neo-Freudians by asserting the role of the intellect: a position that, historically, represents the grafting of contemporary concepts on the Western intellectual tradition. In his *The Intrapsychic Self: Feeling, Cognition and Creativity in Health and Mental Illness,*™ he has described the fundamental stages of human development as a succession of the three categories of primary symbolic cognition (phantasmic stage of inner reality followed by the endocept of the preverbal level and the preconceptual level of thinking), secondary conceptual thinking, and tertiary thinking or creativity. Slowly

Arieti has arrived at a phenomenological view of the human personality that has considerable relevance for future developments.

Schizophrenia

Schizophrenia has remained to the present the most studied, yet the most baffling, of the various psychiatric syndromes, whether it is considered as a "disease" according to the European tradition (Kraepelin, 1896, Bleuler, 1911) or as a "reaction" according to Adolf Meyer's philosophy; that is, whether the emphasis is put on its difference from neurosis or, conversely, on a continuum of the neurotic process. Some genetic studies, especially those on twins carried on at the New York Psychiatric Institute by F. Kallman and then by J. Rainer, have thrown some light on this issue, at least in terms of a premorbid personality due to genic factors developing into a schizophrenic process under the influence of environmental factors.

In the late thirties the empirical approach of shock therapies was emphasized, followed shortly thereafter by the psychosurgical procedures (in this country especially by W. Freeman and J. Watts). This overshadowed the therapeutic method of "total push," geared at a massive utilization of all the patient's resources in the context of the hospital setting, as well as the biological research carried on in a few places, notably at the Worcester State Hospital by R. Hoskins and associates. Such a trend was resumed in the

midfifties, following the introduction of chemotherapy, resulting in a variety of studies and hypotheses (disturbance of the catecholamines, faulty epinephrine metabolism, serotonine blockade, pathological transmethylation, taraxein or blood protein factor, presence of the plasma protein alpha-2 globulin, finally urinary discharge of dimethoxyphenylethamine [DMPEA]).

On the psychological side the American contribution has focused on the notions of ego integration, "pseudoneurotic schizophrenia" (A. Hoch and P. Polatin) or "ambulatory schizophrenia" (G. Zilboorg), "early infantile autism" (L. Kanner), "symbiotic psychosis" (M. Mahler), other child schizophrenic syndromes (L. Render, L. Despert, B. Rank, W. Goldfarb, L. Eisenberg, and others). In the above-mentioned *Interpretation of Schizophrenia,* S. Arieti—on the basis of some fundamental notions on paleological thinking enunciated by E. Von Domarus—has indicated that the schizophrenic way of thinking is based on "primary classes" (that is, Freud's primary process) instead of "secondary classes" (that is, the secondary process of the Aristotelian logic). Examples of such primary thinking are the spontaneous productions of patients (as in the famous Schreber's "Memoirs"), which are increasingly assessed today from the intrinsic perspective of the psycho- pathological process rather than from their difference from the normal process of thinking.

In recent years many studies in this country have focused on the issue of

the faulty ego development of the patient in relation to his family, already anticipated years ago by the notions of "pseudocommunity" (N. Cameron) and loss of "consensual validation" (H. Sullivan) in paranoid patients. From 1956 on the so-called Palo Alto group (G. Bateson, D. Jackson, J. Haley, and J. Weaklan) has concentrated on the "double-bind" theory of schizophrenia, based on the ambiguous message that the schizophrenic receives from his family members, and on the concept of "pseudomentality," that is, the similarities between the disturbed logic of the schizophrenic and the disturbed interpersonal patterns of his family. Along similar lines T. Lidz and associates at Yale have found evidence of deficiencies of ego nurturing in schizophrenic patients.

The literature of the last decade—for example, *The Origins of Schizophrenia* by J. Romano, *Family Process and Schizophrenia* by Mischler Waxier, *The Meaning of Madness* by C. Rosenbaum and co-workers, and *The Schizophrenic Reactions* by R. Cancro,—has been influenced by the above-mentioned concepts. The various books of the British psychiatrist R. D. Laing have had considerable resonance in this country (so to justify their mention here). Laing's interests have shifted from the phenomenological discussion of the inner process of schizophrenia *(The Divided Self,* 1960), to the dynamics of the communication patterns (*The Self and Others,* 1961; *Sanity, Madness and the Family,* 1964), and recently to a metapsychological position calling for major social and political reforms to make possible the reinsertion of the

schizophrenic into society *(The Politics of Experience,* 1967; *The Politics of the Family,* 1969).

Depression

Like schizophrenia, depression has been considered either as a disease (Kraepelin) or as a progressive worsening of a neurotic condition up to a "reaction type" of personality (Meyer's school). No matter what concept psychiatrists adhered to, they came to be increasingly influenced by Freud's famous paper on "Mourning and Melancholia" (1917), until in the forties the attention shifted to the treatment of depression by means of shock therapies.

The emphasis of the British psychoanalytic school (M. Klein) on a normal depressive position in the earlier stages of life never had too much following in this country. American contributions, instead, centered on "anaclitic depression" (R. Spitz) resulting from severe emotional deprivation in infancy and on "bereavement" (E. Lindemann) as a critical condition conducive to maladjustment. Since the introduction of chemotherapy in the midfifties, a great deal of research has focused on the biochemical aspect of depression, such as the antidepressant activity of the inhibitors of monamine oxidase (IMAE), the "catecholamine hypothesis" related to deficiency of noradrenaline, and the effectiveness of lithium carbonate in the treatment of the manic phase of the depressive condition.

All this should not overshadow the advances made in the psychodynamic understanding of depression. In particular, Arieti, aside from the common form of self-blaming depression, has described the "claiming type" of depression, in which there is a loss of the "dominant other," that is, of the idealized parental figure toward whom the patient is dependent. Moreover, these types of patients present a "fear of autonomous gratification"—that is, independent of external approval—and their severe ego defect neurosis makes them unable to transform the interpersonal into the intrapsychic; thus they remain quite vulnerable to the loss of sources of self-esteem.

Worth mentioning are the monographs published on manic-depressive psychosis by L. Beliak, on depression by R. Grinker and associates, and on pharmacotherapy of depression by A. Hordern, J. Cole, and J. Wittenbom. From the perspective of epidemiology and public health—which has recently received a great deal of attention along with the biochemical and the dynamic orientations— measures to deal with acute depressions (0.5 to 2 percent of the general population) include 24-hour emergency assistance in many American cities and a variety of recommendations by the Center for the Study of Suicidology, established at the National Institute of Mental Health in Bethesda, Md.

Psychosomatic Medicine

In the thirties a number of psychoanalysts "rediscovered" the centuries-old belief in the influence of the mind upon the body in the wake of Freud's original concept of somatic compliance in the mechanism of hysteria. Certain diseases—peptic ulcer, asthma, rheumatoid arthritis, colitis, dermatitis, hypertension, and hyperthyroidism—were considered as mainly psychosomatic (the ample monograph by F. Dunbar in 1943 is typical).

Under the overall influence of Freud's theory of anxiety (1926), F. Alexander and pupils from 1932 carried on a great deal of research on psychosomatic conditions, which led to the concept of "specificity," that is, of a definite correlation between each one of these conditions and a particular emotional conflict (for example, repressed hostility in hypertension). No matter how meaningful the study of psychological factors has been (such as the correlation between dreams and the biological phases of the menstrual cycle by T. Benedek), the presence of a particular preexisting organ vulnerability (constitutional factor "X") under conditions of stress has been assumed by practically everyone (for example, by J. Mirsky and associates in cases of duodenal ulcer by measuring the secretion of serum pepsinogen).

Other researchers in the field of psychosomatic medicine have made use of Cannon's emergency theory, of Selye's stress theory, of Schur's resomatization concept, of the metapsychological postulates of Hartmann and of Rapaport, of hypnosis, of projective techniques, of verbal behavior in

particularly structured interviews (Deutsch's "associative anamnesis," open-end medical interview of the Rochester group), or simply of casual happenings (such as the famous case of a gastric fistula illustrated by G. Engel and associates). All this research has brought up a number of issues: mechanism of expression of the "body language," interplay of voluntary and involuntary innervated systems, alternation of psychosomatic and psychotic conditions, and so forth.

Among the important publications in this field are F. Alexander's *Psychosomatic Medicine,* T. Benedek's *Psychosexual Functions in Women,* F. Deutsch's *On the Mysterious Leap from the Mind to the Body,* A. Garma's *Peptic Ulcer and Psychoanalysis,* and G. Engel's *Comprehensive Psychological Development in Health and Disease.* From the historical perspective two factors stand out: (1) the methodological approach has shifted from the exclusive psychoanalytic to an interdisciplinary one, inclusive of biochemists, internists, and behavioral scientists; and (2) the various theoretical models of psychosomatic disorders based on a closed system appeared to be superseded by models based on an open system, as that presented by the general system theory.

The Psychoanalytic School

The study of the life and work of Freud has continued to be the subject

of a number of studies in the last two decades, typically the three-volume monograph by E. Jones completed in 1957. Such a monograph typified the mythical representation of Freud's message to which he himself unconsciously gave a prophetic character. Since then, with the help of newly published material—such as Freud's correspondence with some pupils and friends and the minutes of the early Vienna Psychoanalytic Society— important historical studies have appeared by various authors. Controversies have arisen concerning Freud's academic career and his involvement in the suicide of V. Tausk, author of the classical paper on the "influencing machine" in schizophrenia (1919).

All these studies have been overshadowed by the monographs by E. Erikson on Luther (1958) and on Gandhi (1970), which presented an entire historical period from the perspective of the development of one person, thus opening the new field of psychohistory. This has signified a new advance in the application of psychoanalytic insight to literature and the figurative arts, which has had a long tradition in Europe as well as in this country.

Clinical Developments

The most important event in the history of psychoanalysis has been the shift of emphasis from the unconscious to the ego (mainly A. Freud's *The Ego and the Mechanisms of Defense* and H. Hartmann's *Ego Psychology and the*

Problem of Adaptation), which occurred in the late thirties, shortly before the exodus of a large number of psychoanalysts from central Europe to this country. Freud's anticipation at the occasion of his lectures at Clark University in 1909 that psychoanalysis would receive such a great acceptance in the United States to the point of losing its identity appeared to be confirmed.

Actually the bulk of the psychoanalytic movement remained faithful to Freud's traditional teaching based on the integration of empirical therapeutic procedures and theoretical notions of the structural, economic, genetic, and topographical aspects of the mind, as in Fenichel's classical *Psychoanalytic Theory of Neurosis* (1945). The above-mentioned studies on ego psychology, as well as the research on psychosomatic medicine carried on at the Chicago Psychoanalytic Institute under F. Alexander and the new perspectives presented by the neo-Freudians (C. Thompson, Fromm, H. Sullivan), did not have a significant impact until the fifties.

Here mention at least should be made of the outstanding American representatives of the psychoanalytic movement and their particular area of interest: Helene Deutsch for psychology of women; Theresa Benedek for psychosexual disorders of women; Franz Alexander, Carl Binger, Flanders Dumbar, Thomas French, and Roy Grinker for psychosomatic medicine; Felix Deutsch and Maurice Levine for integration of medicine and psychoanalysis; Jules Masserman for experimental neuroses; Spurgeon English, David Levy,

Gerald Pearson, and Emmy Sylvester for emotional disturbances in childhood; Erich Lindemann and Nathan Ackerman for family dynamics; Frieda Fromm Reichmann and Gustav Bychowski for psychotherapy of psychosis; Kurt Eissler for psychotherapy of delinquents; Abram Kardiner, Kenneth Appel, Greta Bibring, Phyllis Greenacre, Ives Hendrick, Robert Knight, Lawrence Kubie, Bertrand Lewin, Sandor Lorand, Karl and William Menninger, Herman Nunberg, Clara Thompson, Gregory Zilboorg, and many others for various clinical matters.

In particular, a few words should be said regarding the work of Franz Alexander, which spanned three decades of uninterrupted creativity. Particularly important are *Psychoanalytic Therapy* (1946), *Studies in Psychosomatic Medicine* (1948) for its many innovating techniques, and *Our Age of Unreason and Western Mind in Transition,* dealing with broad cultural issues; his various papers collected under *The Scope of Psychoanalysis* (1961) focus especially on the three dynamic principles of homeostasis, economy, and surplus energy. Among the other important American contributors, Thomas French has attempted to represent psychoanalysis as a process of progressive adaptation to achieve integration.

Theoretical Developments: Ego Psychology, Life Cycle

The emphasis on the ego that became prominent in the forties left

unsolved the issue of its genesis. In the fifties H. Hartmann, E. Kris, and R. Loewenstein tried to explain the development of the ego from an undifferentiated state of id-ego under the influence of (1) congenital ego characteristics, (2) primary instinctual drive, and (3) external realities conducive to ego development.

The main advance related to the concept of adaptation, which was anticipated by H. Nunberg and thoroughly investigated by D. Rapaport, who defined it as the balance of ego autonomy from the id and ego autonomy from the environment. The adaptive point of view was integrated with the genetic one in Hartmann's definition of the ego as the matrix of the personality, mastering the apparatus of internal and external motility and the perception, contact with reality, and inhibition of primary instinctual drives.

Other theoretical developments deal with the role of the somatic ego related to the body image, the concepts of "ego strength," of "area of the ego free of conflicts," and of "neutralized energy" (that is, desexualized and aggression-free energy), and the role of introjection and identification in the formation of the ego. All this has come to signify historically a rapprochement between psychoanalysis and genetic psychology, this latter represented mainly by H. Werner and J. Piaget. In fact, Piaget's books became significant for American psychiatry in the last two decades coincidentally with the advent of ego psychology, leading to attempts to compare psychoanalysis

with the school of Geneva (P. Wolff, J. Anthony, and others).

Aside from this the main innovation consists of the concepts developed in this country by the Danish-born and Viennese-trained E. Erikson, a highly creative personality imbued with literary gifts. Erikson views the personality from the perspective of a comprehensive life cycle, in which the "normal" or "normative" rather than the pathological acquires preeminence. Erikson's two most celebrated books, *Young Man Luther* (1956) and *Gandhi's Truth* (1969), represent the best example of an entire historical period viewed in the light of the individual dynamics of an important figure. In other publications *(Identity and Life Cycle,* 1959; *Insight and Responsibility,* 1964; *Identity: Youth and Crisis,* 1969), all stemming from his basic *Childhood and Society* (1950), he has brought to the fore the identity crisis of adolescence in American society and the basic stages of the life cycle. These latter (in succession "hope," "will," "purpose," "skill," "fidelity," "love," "care," "wisdom"), which he has called "basic virtues," can be easily connected with the fundamental "virtues" of the Judeo-Christian tradition. His views on adolescence have come to be very relevant in light of the growing impact of youngsters in the American cultural scene. Erikson's work has influenced many others (as typically represented by the important volume *The Person* by T. Lidz) and transcends the field of psychoanalysis proper, so one may justifiably question whether Erikson belongs to this school.

New Psychoanalytic Trends

The difficulty of separating theoretical from practical issues has been a constant one in the psychoanalytic school. By and large, however, most American psychoanalysts have remained faithful to the basic principles established by Freud.

As the early generation of European-born psychoanalysts is slowly disappearing, the relevance for psychoanalysis of the biological sciences, on the one hand, and of the social sciences, on the other hand, is being recognized. The American Academy of Psychoanalysis, established about 15 years ago, has represented this new trend, as evidenced by the proceedings of the meetings edited by J. Masserman under the title *Science and Psychoanalysis.* In the collaborative volume *Modern Psychoanalysis: Neiv Directions and Perspectives* edited by J. Marmor, the views of the main exponents (R. Grinker, J. Ruesch, etc.) of the integration of psychoanalysis—conceived of as an open system —with biological and social sciences are clearly stated: use of findings from the fields of communication theory, electrical engineering, cybernetics, information theory, automation, and computing; consideration of adaptional aspects derived from information, self-regulatory, and transactional systems and consideration of the fields of forces in which the therapeutic relationship takes place; in general, replacement of a "closed system" based on the death instinct, the narcissistic

drives of the ego, and the isolation of the psychotherapeutic relationship with an "open system" (von Bertalanffy, 1962) as a "reciprocal and reverberating process," a "transaction, rather than self-action or interaction, which is the effect of one system on another, is the relationship of two or more systems within a specific environment which includes both, not as specific entities, but only as they are in relation to each other within a specific space-time field" (Grinker, 1968).

It is to be hoped that the introduction of biological and social dimensions in the reformulation of psychoanalytic principles will result in a much needed clarification of concepts, elimination of tautologies, and improvement of the communication between psychoanalysts and scientists from other fields. As an example of this, the analysis of the symbolic-linguistic system, which is basic in the psychotherapeutic relationship, is being investigated with the help of a new methodology.

Research

As mentioned above, the American contribution to psychoanalysis has mainly consisted in the clarification and, if possible, the measurement of some of the classical findings by the early psychoanalysts. Among the first examples of this trend, quite often represented by psychologists, is the survey of psychoanalytic data published by R. Sears in 1945. The difficulties inherent

to research in psychoanalysis—especially impressionistic bias by the observers, the problem of experimenting with human subjects, and the question of confidentiality—have not been overcome even in the last two decades, when advances were made in the methodological approach to psychiatric research.

From the developmental perspective, in the last 25 years three main areas have become prominent in psychoanalytic research: assessment of psychoanalytic tenets in various experimental situations, observation of child development in terms of psychoanalytic theory, and measurement of the results of psychoanalytic therapy. In the first area, the research on experimental neurosis—originally introduced by J. Masserman and then by J. Dollard and N. Miller in their classical *Frustration and Aggression*—has been extended more recently to the areas of sleep, hypnosis, sensory deprivation, and mother-child relationship by a number of scientists (H. Middell, H. Harlow, and others), resulting in a rapprochement between psychoanalysis and conditioning. In the second area, a number of centers on child development and treatment have undertaken research projects; perhaps the most important one (following the early studies in the forties by D. Levy and by R. Spitz) is that carried on by A. Freud and coworkers at the Hampstead Child Therapy Clinic in London. In the third area falls the Menninger Psychotherapy Research Project, initiated in 1954 and still in progress; it is hoped that this will result in findings more meaningful than those presented

in the Report of the Ad Hoc Committee on Central Fact Gathering of the American Psychoanalytic Association.

Present State of the Psychoanalytic School

When the first edition of this *Handbook* was published in 1959, this historical chapter was presented from a perspective in which psychoanalysis occupied a prominent position. Today this is no longer the case, as it has become clear that psychoanalysis is going through a progressive decline following the high peak it reached in the mid-fifties. This is reflected in the expectation of some segments of the population, in the acceptance of psychoanalytic modes of treatment, and ultimately in the change of self-image of the young psychiatrist, who does not identify any longer with the typical sophisticated, reserved, and well-to-do psychoanalyst.

This is not to say that the psychoanalytic tenets based on the development of the personality from the unconscious matrix in the context of family relationships have been replaced by other more relevant systems. Rather, the attitude of many toward these tenets, especially when not sufficiently proven, has become increasingly critical, and attempts are made to view them from a broader interdisciplinary perspective. Even before the advent of community psychiatry, criticism of the official position of the psychoanalytic association controlled by Freud and his disciples was very

vehement, resulting in a number of secessions: in this country, for instance, the founding of K. Horney's American Institute for Psychoanalysis, of W. A. White's Institute, and of T. Reik's Society for Psychoanalytic Psychology. The other two major issues of the integration of psychoanalysis into medical schools (for example, at Columbia University, the New York Medical College, and the Downstate Medical Center in Brooklyn) and of the exclusion of lay analysts from official recognition (with the exception of very few, such as E. Kris, B. Bornstein, B. Bank, and especially E. Erikson) were particularly debated by the American Psychoanalytic Association, which, founded in 1911, acquired autonomy from the International Psychoanalytic Association in 1938, at the time of the immigration of a large number of analysts from Europe.

While for many years, as it will be shown in the next section of this chapter, the question centered around the acceptance, or rejection, of the official position of the psychoanalytic group, today the main issue concerns the very relevance of psychoanalysis in view of the spread of the community psychiatry movement, which has received massive political and financial support. The reaction of psychoanalysis to this movement has been far from consistent and uniform; it has been punctuated by criticism of community psychiatry for disregarding the basic dyad patient-doctor relationship and training in long-term psychotherapy in order to follow ill-defined methods of treatment and community approaches. All this does not mean that

psychoanalysis is dying, as some sensational journalistic reports seem to indicate, but rather that it is increasingly seen as a specific technique instead of a general philosophy of treatment.

Other Schools and Trends of Psychoanalytic Derivation: Jung, Rank, Adler, Reik, Reich, Klein

Aside from some basic notions presented early in his career and absorbed into the mainstream of the psychoanalytic school (mainly introversion and extroversion, complex and collective unconscious), the work of the Swiss Carl Gustav Jung (1875-1961) has received very little notice here. One reason is that his pupils, being of non-Jewish extraction, did not have to emigrate to this country. Particularly ignored is his late production, which has been exceedingly influenced by mystical, esoteric, and religious concepts not very palatable to the pragmatic American mind. Despite the availability of his main writings in this country for many years (and the current publication of his complete works by the Bollingen Foundation), Jung's ideas have found followers mainly in Switzerland and in England (especially M. Fordham, F. Fordham, Y. Jacobi, and A. Jaffe) and in artistic rather than in psychiatric circles.

In contrast to Jung, Otto Rank (1884-1939) brilliant and favored pupil of Freud, has had a considerable following in this country. His influence, however, results not so much from his original concepts—birth trauma, birth

of the hero, Doppelgang, and other literary and artistic themes (presented in the journal *Imago,* which he directed)—but from the so-called functional school of social work that he established at the University of Pennsylvania and that was continued by his pupils V. Robinson and J. Taft.

In regard to Alfred Adler (1870-1937), his basic notions of inferiority feelings and of organ inferiority have become universally accepted, in spite of his bitter separation from Freud's school in 1911, followed by the founding of the Society for Individual Psychology. In this country, aside from a few pupils (A. Ansbacher, R. Dreikurs, and others), important aspects of his work— notably his application of psychoanalysis to education, resulting in the child guidance movement—have been almost entirely forgotten, probably because of his rather unassuming personality, unconcerned with academic recognition, and because of the poorly organized style of his writings, directed to the general public rather than to professionals.

Other well-known analysts who worked in this country for many years following their arrival from Europe include Theodore Reik (1888-1969), whose books on various clinical aspects of psychoanalysis have met with success, and Wilhelm Reich (1897-1957), who early in his career introduced the innovating notion of "character analysis" (which anticipated ego psychology), then attempted an integration of psychoanalysis and Marxism (very recently brought to the fore again), and eventually became involved in

the controversial "discovery" of "orgone" energy as the basis of life.

Finally the "English" school of the German-born Melanie Klein (1882-1960) has had very little impact in this country. Her main views on the development of the superego in infancy (anticipated by her teacher, K. Abraham), on the crucial role of the introjection of "good" and "bad" objects, and on a normal "depressive position" early in life have been considered too overdetermined by the American mentality concerned with environmental influences. M. Klein's main contribution lies in her pioneering use of play therapy in the twenties and in some anticipations of the psychoanalytic therapy of psychotic children.

Original American Contributions. Neo-Freudians, Cultural, and Interpersonal Schools: Rado, Horney, Sullivan, Fromm

Rado, Horney, Sullivan, and Fromm typify the original American contribution to the psychoanalytic movement. Although all of them, with the exception of Sullivan, were European-born, their work has taken place almost exclusively in this country. They have all been influenced by the Swiss-born Adolf Meyer (1866-1950), the founder of the school of psychobiology, which had considerable impact on American psychiatry—probably because of its optimistic view of human nature in contrast to Freud's pessimism—and which was represented by a large number of pupils who eventually acquired leading academic positions in this country as well as abroad. Aside from its

eclectic orientation and broad acceptance, psychobiology is generally considered to have facilitated the introduction of the psychoanalytic movement in this country.

The "adaptational psychodynamics" of Sandor Rado (1890-1972), based, like Meyer's philosophy, on an eclectic methodology and on an evolutionary biological orientation, aims at describing the hierarchical levels of central integration and control of the organism's motivation and behavior.

The German-born Karen Horney (1885-1952), an early pupil of Franz Alexander in Chicago, became widely known for her many books directed to the general public, in which she stressed the importance of environmental influences at variance with the rigid aspect of Freud's doctrine of the instincts and of family dynamics (for example, the dominant male role). Her explanation of neurosis as "moving toward," "moving away," and "moving against" and of defenses as "self-effacement," "expansiveness," and "resignation" can be viewed as an anticipation of today's clinical pictures of alienation and lack of emotional involvement.

Harry Stack Sullivan (1892-1949) is unquestionably the most original and significant representative of neo-Freudianism. Under the influence of social scientists (R. Benedict, M. Mead, E. Sapir, H. Lasswell, and others) he departed from Freud's rigid notions of the individual development of the

personality (that is, stages of libido, oedipus complex) and elaborated notions based on various modalities of experiencing interpersonal relationship ("prototaxic," "parataxic," and "syntaxic") and on the central role of anxiety as experienced disapproval from others, leading to the appearance of substitutive neurotic and disintegrative psychotic symptoms. Today Sullivan is especially remembered in American psychiatry for his pioneering attempt to view psychotherapy as a mutual learning experience between patient and doctor and to consider even psychoses as treatable through a correction of distorted processes of communication.

Also geared to the general public are the many volumes of the German-born Erich Fromm (b. 1900), in the past associated with the William Alanson White Institute in New York City. His presentation of personality types ("receptive," "exploitative," "hoarding," "marketing," and "productive") reflects his dramatic view of man in conflict between individual aspirations and dehumanizing collective forms of life. Fromm's writings, in which he has paid tribute to both Freud and Marx, have an appealing and engaging style, but are rather peripheral to the central theme of psychiatry proper. The same can be said of the philosopher Herbert Marcuse (b. 1898), whose humanistic defenses of man from the Marxist perspective have been taken as a symbol by the New Left.

It is too early to pass judgment on the historical significance of Fromm,

Marcuse, and others. For the neo-Freudians, instead, the comprehensive works by R. Munroe, C. Thompson, and others are available.

Existentialist Schools

Since the existentialist movement pertains essentially to philosophy and developed mainly in Europe, it is important to state that, like the rest of this chapter, this presentation deals exclusively with the *American* developments of existentialism in relation to psychiatry and presupposes a basic knowledge of its main tenets. The matter is complicated by the vagueness of the core and boundaries of existential psychiatry, which inherently defies any attempt at categorization into a definite school with clearly established teaching.

Rather, it is generally accepted that existentialism, a fundamental theme of human existence from the Greeks on, tends to become significant at times of general insecurity and weakening of social institutions, leading to a defense of the uniqueness of the individual person. The sources of the existential movement (mainly Kierkegaard, Dilthey, Husserl, Buber, and Heidegger in Europe and W. James in this country) have been well established and presented in comprehensive form, especially in the monograph by H. Spiegelberg. Also it has been said that the essence of the psychotherapeutic relationship includes an existential motive.

The fact remains that in this country, probably in relation to the

awareness of new social dimensions (poverty, alienation, racial conflicts, and so forth), existential psychiatry came to the fore in the mid-fifties. Various works by European exponents of existential psychiatry (K. Jaspers, L. Binswanger, M. Boss, and others) became available in translation; a comprehensive volume on this field (*Existence: A New Dimension in Psychiatry and Psychology,* edited by R. May, E. Angel, and H. Ellenberger, 1958) was published; three journals were founded with the support of G. Allport, C. Rogers, E. Weigert, C. Biihler, H. Murray, and others. The original American contributions worth mentioning are R. May's *The Meaning of Anxiety* (1950), P. Tillich's *The Courage to Be* (1953), and A. Maslow's *Toward a Psychology of Being* (1962); Maslow is a representative of a "third force" in psychology, between behaviorism, on the one hand, and psychoanalysis, on the other hand.

Today, a decade later, it safely can be said that the original impetus of the existential movement has subsided. Even the publications of Erwin Strauss, a distinguished European-born existentialist who has been active in Lexington, Ky., for more than two decades, have received very little notice. It appears that the reaction of many disenchanted with the traditional American style of life has taken the form of "irrational" group expressions (such as the acceptance of Marxism, the spread of collective movements from the hippies to encounter sessions, the refuge into all kinds of beliefs from occultism to Far Eastern practices), rather than of an individual response like in Europe.

New Trends: Ethology, General System Theory, Ecology, Structuralism

These various trends, though apparently heterogeneous, have in common two main aspects: (1) their appearance in the last two decades or so, in response to dissatisfaction with current concepts of human behavior as not relevant to the new needs of man's changing role under the pressure of collective systems; (2) their interdisciplinary approach, from comparative neuroanatomy to anthropology, sociology, electrical engineering, and environmental planning, aimed at facing today's overwhelming problems of population explosion, environmental contamination, and rise of underdeveloped nations by defending the humanistic core of the individual without escaping from the world, to the point of constituting a sort of "new utopia" (W. Boguslaw). Also two of them, ethology and structuralism, are of European origin and based on innate and congenital postulates; the other two, general system theory and ecology, are of American origin and based on environmental and behavioristic postulates.

Their relevance to psychiatry can be summarized in a few points. Ethology, initiated by Lorenz, Tinbergen, and others, is mainly related to the findings of developmental psychology (R. Spitz, P. Wolff) and comparative development (H. Harlow). General systems theory (L. Bertalanffy) based on the notions of homeostasis, transactional relationship, and communication and information processes, has resulted in works by R. Grinker (*Toward a*

Unified Theory of Human Behavior), by K. Menninger *(The Vital Balance,* a new classification of mental disorders based on this theory), by S. Arieti (who has stressed that mental dysfunction is a system disturbance rather than a loss of single functions, especially in schizophrenia), and by others (J. Ruesch's concern with the human aspects of systems, J. Spiegel's notion of foci in a transactional field, L. Frank's views on organized complexity, J. Miller's behavioral theory as having relevance for community mental health), all presented in the recent volume *General Systems Theory and Psycluatry,* edited by W. Gray, F. Duhl, and N. Rizzo. Ecology, rapidly seen as important for psychology (for example, in *Environmental Psychology: Man and His Physical Setting,* edited by H. Proshansky, W. Ittelson, and L. Rivlin) has resulted in the new ecological model of mental illness and treatment based on the interplay between the individual and his environment (E. Auerswald). Finally structuralism (mainly founded on the writings of the French anthropologist C. Levi-Strauss) is still too new for its relevance for psychiatry to be seen, but it has definite connections with psycholinguistics, communication theory, and transcultural psychiatry, as well as psychology (for this latter, mainly in the book recently published on structuralism by J. Piaget).

Overall Development of Psychiatric Treatment: From Hospital to Community

The expression "community psychiatry" has become increasingly popular in the last ten years. From the historical perspective of this chapter,

two points are important in relation to this issue: the developments that led to the preeminence of community psychiatry and the definition of its core and boundaries vis-a-vis other collateral fields.

In regard to the first point, throughout history the mentally ill have been seen in different ways, from being possessed by devils to being emissaries of gods, and consequently worshiped, tortured, or simply neglected. Recent historical studies (mainly by E. Ackerknecht, G. Rosen, I. Galdston, M. Foucault, and others) have attempted to investigate the social and cultural dimensions underlying these various attitudes. In this country a progression can be followed from the emphasis on institutionalization during the late nineteenth century to the recognition of the value of treating the patient in his own environment, to the awareness of prevention of mental disorders, and finally to the ambitious plan of making psychiatry available to everyone at the community level. Some historical presentations of community psychiatry (by J. Ewalt and P. Ewait, J. Brand, W. Barton, A. Freedman, W. Ryan, I. Galdston and A. Rossi) are available.

In regard to the second point, community psychiatry has to be differentiated from social psychiatry. This latter, first defined in this country by T. Rennie in 1956 as concerned with individual and collective forces in relation to adaptation and psychopathology, has been from time to time especially interested in environmental (F.Redlich and M. Pepper).

sociocultural (A. Leighton), transcultural (E. Wittkower), ecological (J. Ruesch) and interdisciplinary (N. Bell and J. Spiegel) aspects. In general, the focus of social psychiatry is on theory and research in relation to sociological theories and ecological models.

Instead, the focus of community psychiatry —concretely represented through the concept of "catchment area" as an area of 50,000-75,000 people identifiable for common ethnic, social, and cultural dimensions—is on treatment and on prevention. Treatment is carried on in a variety of ways— also due to the different ethnic, cultural, and religious backgrounds of various groups in this country—justifying the criticism of being "a movement without a philosophy." Prevention relies heavily on the fields of epidemiology and public health and has achieved recognition especially through the many studies published by G. Caplan, who is responsible for the subdivisions of primary, secondary, and tertiary prevention. It is likely that the various schools of community psychiatry now operating in this country (especially important are those at Harvard, Columbia, and the University of California) will contribute in time to the clarification of this new field.

The Movement toward Community Psychiatry: "Action for Mental Health"

The movement of community psychiatry, which was officially initiated in 1961 with the publication of *Action for Mental Health*, represented the

culmination of a long period of incubation and the convergence of various trends that can be followed for a considerable period.

Prior to World War II some developments anticipated themes central to community psychiatry: opening of outpatient clinics for adults and then for children, organization of psychiatric social work, A. Meyer's pioneering views of today's concept of "catchment area," interdisciplinary input by sociology and anthropology, lay involvement in the mental hygiene movement, and new therapeutic optimism derived from collective forms of treatment.

It is well known that World War II emphasized the magnitude of psychiatric disorders and the need for a national program to adequately face this issue. In succession a series of steps were taken: establishment of vast facilities for treatment and training by the Veterans' Administration; passing of the Hill-Burton Act for federal assistance to allocate psychiatric beds in general hospitals (which now number more than 30,000); foundation of the National Institute of Mental Health in 1949, which, under the long leadership of R. Felix, developed a Community Services Branch; participation in research on community aspects of mental health by some foundations. notably the Milbank Memorial Fund.

Meanwhile, in the psychiatric field the social structure of the mental hospital was first described by A. Stanton and M. Schwartz in their pioneering

study *The Mental Hospital* (1954), carried out at Chesnut Lodge in Rockville, Md.; this received ample recognition and was followed by others (for example, *From Custodial to Therapeutic* and *The Patient and the Mental Hospital,* both edited by M. Greenblatt, *et al.).* Also the important research on the sociological aspects of psychiatric treatment by A. Hollingshead and F. Redlich and the "Mid-Town Study" on psychiatric epidemiology in Manhattan by L. Srole, *et al.,* were published.

All this, as well as other developments, eventually had an impact on the political scene. Community Mental Health Acts to assist local community programs were approved (first in New York State in 1954), and the annual Governors' Conference on Mental Health offered the impetus for passing adequate legislation. As a result of the Mental Health Study Act of 1955, the Joint Commission on Mental Illness and Health was established under the leadership of K. Appel and L. Bartcmeier to make an assessment of the system of treatment and care of the mentally ill, identify needs, and propose recommendations.

At the end of five years of work the Commission's Chairman J. Ewalt and collaborators found that the 13,000 psychiatrists then available were largely insufficient to take care of the large number of people in need of assistance; the 1,250 state institutions, where the great majority of the 700,000 mental patients were, tended to be overcrowded and understaffed; moreover, less

than one million people were treated as outpatients, although statistics showed that 10 per cent of the general population were affected by nervous and mental illness.

The Commission's recommendations centered around three points: (1) improvement in the utilization of manpower by gearing psychiatrists toward community mental health and relying on the help of other professionals and nonprofcssionals; (2) opening of many new facilities, such as clinics, psychiatric wards in general hospitals, and centers for rehabilitation; (3) provision of adequate funds at local, state, and federal levels.

Aside from the widely distributed and comprehensive volume, *Action for Mental Health,* nine other books were published on the following topics: concepts and public images of mental health, economics, manpower, community resources, epidemiology, role of schools and churches in mental health, new perspectives on mental patient care, and research resources in mental health. A basic suggestion for the implementation of this new approach was to convert large state hospitals into units of no more than 1,000 patients and to provide a mental health clinic for each 50,000 people.

With the support of many professionals and laymen (such as Mary Lasker and Mike Gorman, executive director of the National Committee against Mental Illness), as well as legislators (mainly Senator L. Hill,

Congressmen J. Priest, O. Harris, and J. Fogarty, and A. Ribicoff, then Secretary of Health, Education, and Welfare), proposals to implement the recommendations of the Commission were introduced in Congress. Significant impetus toward the success of this endeavor was provided by the late President Kennedy; on February 5, 1963, in his memorable message to the 88th Congress on mental illness and retardation, he indicated that what was needed was "a national mental health program to assist in the inauguration of a wholly new emphasis and approach to care for the mentally ill—which will return mental health to the mainstream of American medicine, and at the same time upgrade mental health services."

Eventually this political action (described in detail in *Politics of Mental Health,* edited by R. Connery) resulted in the passing of the Community Mental Health Act in 1963, which provided for the establishment of a community mental health center for each "catchment area" of about 75,000 people. Any center had to offer five types of services: inpatient, outpatient, partial hospitalization, emergency and consultation, and education. Other services, such as diagnostic, vocational, training, and research were also recommended, but not mandated. In addition to the $150 million over a three-year period to finance these centers, an amendment to the Act was signed by President Johnson in 1965 to provide federal funds also for staffing. By 1970 more than 400 centers were in operation: some received construction grants, others staffing grants or both. The NIMH budget for that

year was $348 million, while moneys allocated by the states reached $2Vi billion.

Developments in the Pattern of Delivery of Services: Mental Hospitals, Outpatient Clinics, Community Mental Health Centers

Historically services for the mentally ill have developed according to the order followed in the above heading. Mental hospitals first appeared at the end of the eighteenth century in the process of differentiating the mentally ill from all other outcasts of society; the philosophy of "moral treatment" based on the paternalistic approach of the superintendent was carried on successfully in the small, homogeneous private mental hospitals in the early nineteenth century; later on, with the arrival of many immigrants and the expansion of the frontier, the mentally ill were increasingly institutionalized in large state institutions (many built under the impetus of D. Dix's crusade) where treatment became more impersonal and custodial.

Around the second decade of our century, under the influence of several currents (progressivism, psychoanalysis, behaviorism, and others) outpatient treatment for many people affected with emotional disturbances gained momentum. However, the practice persisted of keeping the mentally ill anonymously in large institutions away from the community. At times it reached the point of neglect and despair, as portrayed in *The Shame of the States* by A. Deutsch and in *The Snake Pit* by M. Ward.

Only in the mid-fifties two concomitant developments, the introduction of chemotherapy on a large scale and a more accepting attitude toward mental illness on the part of many, resulted in a substantial improvement in the delivery of services to mental patients. The first important step in this direction was the "therapeutic community" described by M. Jones in England in 1953. As a result of clarification of structures, roles, and role relationship reached in mental hospitals through T groups, sensitivity training, crisis situations, and face-to-face confrontations, there was an improvement in staff-patient interaction and increased participation by patients in the therapeutic program (on such issues as confidentiality, authority, decision making, and limit setting.)

In time other modalities of treatment were introduced, first in Europe and then in this country: "day hospitals" for patients not needing full hospitalization; family care and aftercare services; ex-patient clubs; use of volunteers; assignment of patients from the same geographical area to a "unit" in the state hospital to facilitate contacts with their community. All these pioneering endeavors came to be named the "open-door policy" (M. Jones), that is, a shift from a custodial to a therapeutic setting and from a closed to an open system. "Therapeutic community" has also become a very commonly used expression, not only in terms of the mental hospitals, but also in terms of the community at large. As one would expect, these developments have resulted in a progressive decrease—for the first time in the last 150

years—in the number of hospitalized patients from about 559,000 in 1953 to less than 425,000 fifteen years later.

Recently the notion of "revolving door" has been introduced to signify the flexible approach both of the hospital and of the community, as quite often the problems of the mentally ill cannot be properly met simply by transferring the responsibility for the patient from the institution to his family. Worth mentioning also is the significant role that private mental hospitals (about 170 caring for almost 17,000 patients and involved in the National Association of Private Psychiatric Hospitals) have played in the above-mentioned developments.

The literature on all these events is quite extensive. Among the most valuable works are *The Therapeutic Community* by M. Jones, *The Psychiatric Hospital as a Small Society* by W. Caudill, *Day Hospital* by B. Kramer, *The Prevention of Hospitalization* by M. Greenblatt, *Partial Hospitalization for the Mentally Ill* by Glasscote, et al, *The Day Treatment Center* by Meltzoff and Blumenthal, *The Treatment of Family in Crisis* by Langsley and Kaplan, *Community as Do*ctor by R. Rapaport, *Social Psychiatry in Action: A Therapeutic Community* by H. Wiener, and *The Psychiatric Hospital as a Therapeutic Community* by A. Gralnick.

Outpatient clinics have an important tradition in this country, which can

be traced back to the convergence of various movements of social work, voluntary agency, welfare programs, settlement houses, and others early in this century. The original philosophy of these clinics was eclectic and depended largely on community resources. A number of clinics (281 out of a total of 373 in 1935) served patients discharged from mental hospitals, and most of them were located in the five states of New York, Massachusetts, Pennsylvania, New Jersey, and Michigan.

In the forties and fifties, under the influence of the psychoanalytic school, clinics came to be geared toward long-term treatment of intrapsychic problems by members of various disciplines (mainly psychology and social work) that identified with the psychotherapeutic role of the physicians. Increasingly the philosophy of treatment tended to favor young, intelligent, and sophisticated patients whose values were similar to that of the staff, while the contact with community agencies and schools became negligible.

Around the mid-fifties the country suddenly became aware of the conditions of poverty, neglect, and rejection of a considerable segment of the population (M. Harrington, F. Riessman, M. Deutsch, and others). The fact that middle-class people tended to be treated in clinics while low-class people ended in mental hospitals was well documented by A. Hollingshead and F. Redlich. Slowly many sicker patients, no longer in need of institutional care because of the success of psychopharmacological treatment and the above-

mentioned open-door policy of mental hospitals, came to be treated by outpatient clinics with the help of new techniques, such as family and group therapy.

However, the controversies concerning the role of the approximately 2,000 clinics now existing (organized under POCA, Psychiatric Outpatient Centers of America) are far from over. One of the sharpest critics, G. Albee, has written that "the psychiatric clinics in the United States are treating the wrong people; they are using the wrong methods; they are located in the wrong places; they are improperly staffed and administered; and they require vast and widespread overhaul if they are to continue to exist as a viable institution."'

In the context of the community mental health movement, the philosophy of the clinics tends to be influenced by social factors: new therapeutic modalities aimed at treating low- income and culturally disadvantaged groups, as well as patients in critical need of treatment (adolescents, alcoholics, drug addicts, etc.), are developed; efforts are made to open clinics in rural areas and in Midwestern and Southern states with the substantial help of public moneys and, to a less extent, of insurance coverage.

The main issue remains the identity of the outpatient clinic vis-a-vis the community mental health movement. This is colored by considerable

ambivalence: on the one hand, the nostalgic feeling toward the traditional small clinic whose staff was quite involved with the patients; on the other hand, the commitment to serve as many people from all backgrounds as possible, in the context of the network of medical, social, educational, and rehabilitation services in the community.

Community mental health centers, being only less than a decade old, are difficult to assess from the historical perspective. The complexity of any one of such centers, composed of various agencies staffed by an heterogeneous group and located in areas culturally different, contributes greatly to such difficulty.

Yet ten years from *Action for Mental Health,* some trends concerning the development of community mental health have emerged. It is unquestionable that the great expectations raised initially that this movement would constitute a "third" (N. Hobbs) or a "fourth" (L. Linn) psychiatric revolution are not accepted by many. At best it is accepted that this movement helped considerably to create a climate of more favorable acceptance toward emotional disorders and a more optimistic outlook toward their treatment.

However, it is increasingly recognized that the mental health movement is not a panacea for gigantic social problems, from the Vietnam War to drug addiction to changes in the traditional values of this country (J. Seeley). Too

often existing services, no matter how labeled, have remained unchanged and therapeutic modalities have remained unaffected by this movement; the role of the so-called paraprofessionals or "activators," tom between their commitment to treating the underprivileged and their identification with the professionals, has become controversial.

From an overall perspective the dilemma of the psychiatrist toward the patient, or toward the community forces tending to control the patient, has been brought forward, notably in a dramatic form by T. Szasz. Moreover, criticism has been expressed in leftist quarters, mainly in nonpsychiatric literature, toward the "psychiatrization" of social conflicts" (for instance, turning delinquency and youth unrest into an illness); on the opposite side conservative groups have seen the mental health movement as a plot against patriotism by government infringement on the mental health of the citizens.

Among the professionals it is commonly accepted that this movement, while making good use of principles of epidemiology and of public health, lacks a conceptual foundation, to the point of being called "a movement in search of a theory" (J. Newbrough) or "the newest therapeutic bandwagon" (H. Dunham). From the psychoanalytic viewpoint the approach stressed by this movement has been characterized as "a retreat from the patient" (L. Kubie), and a strong defense of the "medical" (that is, "dyadic") model of the doctor-patient relationship over the "social" model has been voiced by some

(R. Kaufman, L. Kolb).

All this should not deter anyone from recognizing the moral implications of a movement that, in line with the American democratic tradition, attempts to bring help to the largest possible number of people in need. Unquestionably some positive results have been achieved: a more flexible use of professionals reached through a slow reorientation of goals and functions; the integration of many nonprofessionals in the work of each community mental health center; the new pattern of cooperation with social agencies, schools, institutions, and other facilities in the community; the increasing integration of health and mental health services; the progressive acceptance of responsibility toward the emotionally disturbed on the part of local, state, and federal agencies; and last but not least, the more accepting attitude toward mental illness by many segments of the population.

These points, and others, have been brought forward in a number of publications, such as the *Handbook of Community Psychiatry* (edited by L. Beliak), *Perspectives in Community Mental Health* (edited by A. Bindman, R. Williams, and L. Ozarin), *Progress in Com- munity Mental Health* (edited by L. Beliak and H. Barten), as well as in special journals (mainly the *Community Mental Health Journal* and *Hospital and Community Psychiatry).*

Thus far most of the impetus toward community psychiatry has taken

place in the states of the East Coast, in California, and in some Midwestern states. The realignment of national priorities related to the slight economic recession and other social problems of this country indicates that local communities will have to assume most of the responsibilities for the community mental health movement. How this will affect the success of this movement in the long run remains to be seen.

Therapy

Any attempt at modifying the mental functioning of a person has to be viewed from the perspective of the theory of mind and body prevailing in each culture at a particular period. In the Western tradition the centuries- old Aristotelian notion of a body-mind unity was replaced by Descartes' splitting of body and mind in the seventeenth century. Consequently mental disorders, which were traditionally considered in the light of that unity, came to be "discovered" from that time on.

In regard to therapy, the decades between the end of the eighteenth century and the beginning of the nineteenth century saw the rise of mesmerism for neurotic patients and of moral treatment for psychotic patients; later on for several decades therapy was influenced by the organogenic notion of the ascendancy of the body over the mind; psychoanalysis reversed this situation by emphasizing the characteristics of

mental functions and the treatment of neurotic disorders. The psychodynamic trend has persisted to our days, although organic theories of the mind became prominent again in the thirties in connection with the introduction of shock therapies and in the fifties with the discovery of chemotherapy.

While all this justifiably has aroused in many the urge to reach a new unitary concept of body and mind, the orientation of most psychiatrists with the psychogenic or organogenic tradition makes this goal unattainable at present. The need to replace today's hybrid eclectism with a comprehensive formulation of body and mind—perhaps based on the new ecological framework of the general systems theory—may very well constitute the challenge of the seventies.

Organic Therapies

Shock Therapies

The notion that sudden and unexpected events (such as a loud noise, an unpredictable shower, or a fall into the water) may alter the mental status of a person is very old; it was used empirically by some German psychiatrists in the early nineteenth century.

In the late thirties shock therapies were introduced in a matter of a few

years, first in Europe and then in the United States. M. Sakel (1900-1957) initiated insulin coma in Berlin and Vienna; J. Meduna (1896-1964) eardiazol shock in Budapest; V. Cerletti (1877-1963) and L. Bini (1908-1964) electric convulsions in Rome. The first two moved to this country shortly thereafter, so that their therapies became an intrinsic part of American psychiatry, while electric shock was imported here by a few European psychiatrists (mainly L. Kalinowski, R. Almansi, and D. Impastato).

From the historical perspective the significance of shock therapies has been to bring new optimism to the treatment of psychiatric conditions, which had been largely missing in the psychodynamic schools, both in the patients and in the professionals. After the wave of enthusiasm shock therapies came to be limited mainly to electric shock, because of its easy use and safety, and to the treatment of forms of depression. The efforts of many to find the explanation of the intrinsic mechanism of action of shock therapies (based on biochemical abnormalities or on other notions) have been unsatisfactory. Also limited have been the technical improvements, such as use of anesthesia and various substances to achieve relaxation. Worth mentioning also are the psychological implications of shock therapies, that is, the patient's regression and dependence on the staff coupled with symbolic death and rebirth. In the last two decades, in connection with the rise of psychopharmacology, the literature on shock treatment has decreased considerably. The classic book on the subject is *Shock Treatment, Psijchosurgerij and Other Somatic*

Procedures in Psychiatry by L. Kalinowski and P. Hoch, continually brought up-to-date.

Psychosurgery

Archaeological remnants of past civilizations bring evidence that skull trepanation for the purpose of liberating epileptic as well as mental patients from the alleged possession by evil spirits was extensively practiced. Surgical interventions on the brain are recorded in Roman, Byzantine, and Arabian medicine, while, later on, caution prevailed in connection with the discoveries of the delicate functions of the central nervous system.

By the thirties some knowledge had been gathered on the relationship between cortical and subcortical functions on the basis of data obtained from ablation of frontal lobes in monkeys (J. Fulton, C. Jacobsen), from electroencephalography, and from stimulation and inhibition of cortical areas. The Portuguese Nobel Prize winner Egas Moniz (1874-1955) was the first to perform a successful lobotomy in 1936. His technique was imported to this country and widely used for a number of psychiatric conditions in the forties, mainly by W. Freemann and Y. Watts in Washington, D.C., and elsewhere.

Regardless of the new surgical techniques—topectomy, thalathomy, cingulectomy, and others—the opposition to psychosurgery has mounted in professional quarters in regard to the indications for selection of patients and

the postoperative impairment of intellectual functioning and will. Lay and religious groups, from the Catholic Church to Soviet Russia, have condemned psychosurgery on moral grounds. The controversies about psychosurgery have decreased considerably because of its decline and the corresponding rise of psychopharmacology, which can result in a sort of "functional" lobotomy without producing personality changes and moral conflicts. Very recently some of these issues have been raised again in connection with the research by J. Delgado at Yale University on modification of psychotic behavior through electrodes implanted in various areas of the brain.

Psychopharmacology

The field of psychopharmacology, less than two decades old, has become one of the most important in psychiatry. Today's extensive use of "drugs of the mind" has brought forward many similarities between them and a variety of drugs employed in magic-religious ceremonies of healing in preliterate cultures. Comparative research has been carried on by some, often working in interdisciplinary teams of pharmacologists, psychiatrists, anthropologists, and others.

In the history of Western medicine, aside from hellebore in Greek times, the list of the "drugs of the mind" includes antimony, belladonna, hyoscyamus, cannabis indica, quinina, followed in the nineteenth century and

later on by opium, bromides, chloral hydrate, paraldehyde, and finally barbiturates. Mescaline was isolated in 1896 by the German L. Levvin (who published a famous book on the drugs of the mind) " and later synthetized, and its hallucinogenic effects were described in the German literature in this century.

Later on the therapeutic importance of diphenylhydantoin for some forms of epilepsy was proved by the neurologist T. Putnam. In 1938 lysergic acid diethylamide (LSD 25) was discovered by the Swiss chemist A. Hoffmann, and in the forties amphetamines (benzedrine and dexedrine) were studied by G. Alles, while serotonin was isolated by I. H. Page in 1945. By that time extensive use had been made during World War II of sodium amytal and similar compounds in narcocatharsis, narcoanalysis, and narcosynthesis for the intensive treatment of acute breakdowns. On a more theoretical basis research on hormonal substances was carried on in some centers, notably at the Worcester Foundation by H. Hoagland and associates.

The credit for first having used chlorpromazine in psychotic and agitated patients is attributed to the French P. Deniker, H. Leborit, and J. Delay early in the fifties. This opened the way to a great step forward in psychiatry, that is, to a more optimistic view of mental illness on the part of professionals and patients and ultimately of the community. In rapid succession a number of other important drugs were discovered and used: meprobamates by F.

Berger and B. Ludwig (1950); LSD 25 for clinical purposes by J. Elkes; reserpine by the Swiss H. Bein (1956); the antidepressing imipramine by the Swiss R. Kuhn (1957); butyrophenone by the Belgian P. Janssen (1958); chlorprothixene (Taractan) by the Danish R. Ravn (1959); benzodiazepines (Librium) by I. Cohen at the University of Texas (1960); finally the antimanic effects of lithium by the New Zealander J. Cade in the sixties.

Regardless of national boundaries, great rapidity has characterized the use of these new drugs, be these "tranquilizers" (a term first used by F. Yonkman) or "psychic energizers" (a term coined by N. Kline) or "neuroleptic drugs," which is the term commonly used in Europe (originally introduced by Delay and Deniker). Impetus toward research and practical application of psychopharmacology has resulted from the establishment of research centers (mainly the Psychopharmacological Service of the NIMH and the one at St. Elizabeths Hospital in Washington), from the sponsoring of a number of international symposia with the help of private organizations (such as the Macy Foundation), from the foundation of the Collegium Internationale Neuropsychopharmacologicum in 1957, and from the publications of important serial volumes (such as *Recent Advances in Biological Psychiatry,* edited by J. Wortis). Also worth mentioning from the historical perspective is the monograph containing the proceedings held at Taylor Manor Hospital in Raltimore in 1970 by the discoverers of psychopharmacology. From the lively account of the participants one learns about the creative process of discovery,

the interplay of pure research and the interests of supporting drug companies, legal aspects in various nations, and the continuity of the tradition of "drugs of the mind" from preliterate cultures to our civilization.

No matter to what psychiatric school one adheres, he cannot dispute the value of psychopharmacology in alleviating many emotional conditions—especially some that previously required hospitalization. On the other hand, exaggerated expectations about the uncritical use of "psychomimetics" (mainly LSD 25) in the treatment of mental disorders and especially about the power of some drugs to enlarge the field of consciousness and provide new philosophical and religious insights are unrealistic. Concretely many use chemotherapy in conjunction with psychotherapy, regardless of the psychodynamic aspects of the administration of drugs, mainly the orally dependent and the suggestive effects (as proved by some research on placebo). From a broader perspective psychopharmacology has resulted in a much more enlightened attitude toward mental illness on the part of many general practitioners and other physicians and especially the general population at large.

Psychological Therapies

Since the first edition of this book was published, psychological therapies have also undergone a considerable process of reassessment from

the historical perspective. Their importance was unquestionably brought forward by Freud's basic concept of the one-to-one relationship. Following the widespread acceptance of Freud's ideas, for a number of years such psychoanalysts as G. Rohcim investigated healing practices for mental disorders carried on in past or present preliterate cultures.

The innovation that has taken place recently consists in the new methodological approach toward such healing practices by researchers well versed in psychiatry and anthropology (for example, G. Devereux, C. Kluckhohn, A. Leighton, J. Frank, M. Opler). Considerable light has been thrown on the causes of mental disorders in preliterate cultures, be these nonphysical events (that is, power of devils or ancestors and action of words and deeds) or events attributed to the person himself (that is, disregard for certain taboos). Also in the last decade or so, methods of psychological healing stemming from the Greek tradition and their relation to present methods have been made the subject of thorough studies by W. Riese, P. Lain Entralgo, H. Ellenberger, and others.

Psychotherapy has unquestionably become more accepted in this country in recent years, as evidenced by the foundation of the American Academy of Psychotherapy in 1959 and by the annual publication *Progress in Psychotherapy,* edited by J. Masserman since 1956. However, a critical view of the psychotherapeutic process has been advanced by some: for example, J.

Ehrenwald's notion of "doctrinal compliance" to explain the tendency of the therapist to fit everything into his own system. Moreover, the boundaries of psychological therapies have been loosened considerably, not only by the success of nondy- adic modalities, such as family and group therapy, but by the spread of new approaches, from brief therapy and crisis intervention to encounter groups, and by the inclusion of nonprofessionals among the therapists.

Underlying many of these developments appears to be a basic conflict between the traditional Freudian approach based on the doctor-patient relationship in a stable cultural context and the new collective approaches resulting from the urge toward action brought forward by the pressing social problems of this country.

Individual Psychotherapy: Psychoanalytic Psychotherapy and Psychoanalytically Oriented Psychotherapy

For the historian it is intriguing to investigate the causes of a major shift in regard to psychoanalytic therapy that has taken place in the last dozen years. In 1959, when this book first appeared, this chapter was written from the perspective of the preeminence of the psychoanalytic doctrine in the overall field of psychiatry, in terms of expectations from the sophisticated self-image of the psychiatrists, methods of psychiatric training, and doctrinal adherence of most of the psychiatrists in teaching positions.

As a result of many currents, such as the well-documented study by A. Hollingshead and F. Redlich showing that psychotherapy was available only to middle- and upper-class patients while lower-class patients tended to receive somatic therapies in institutions, *Action for Mental Health* (1961) offered a nationwide guideline for delivery of psychiatric services to all the citizens of the nation. Increasingly the traditional psychoanalytic methods have become diluted by emphasizing symptoms at the expense of the basic personality and healthy potential rather than pathology, to the point of fully justifying Freud's prediction that psychoanalysis would become so accepted in this country that it would lose its identity.

This is paralleled by the trend among professionals, either well-trained psychoanalysts or psychiatrists, to make wide use of psychoanalytically oriented psychotherapy and to restrict classical psychoanalysis to few patients in need of such procedure, which, in addition, is costly and available only in some urban areas. Moreover, the tendency toward integration of psychoanalysis in the training curriculum of some medical centers has been the subject of bitter controversies between those inclined to a dogmatic defense of Freud's message and those open to a dialogue with adherents of other schools.

In the attempt to introduce clarity and specificity in psychoanalytic therapy, many new nomenclatures have been presented in the literature.

Aside from the loose distinction of deep versus superficial, insight versus supportive, verbal versus active therapy, descriptions have been offered of listening, clarification, confrontation, interpretation, suggestion, prohibition, and manipulation, and therapeutic techniques have been listed as suggestive, abreactive, clarifying, interpretative, suppressive, expressive, supportive, exploratory, educational, up to paternal and maternal. To the classic "correctional emotional experience" of Alexander and French have been added the intensive psychotherapy of psychosis (Fromm- Reichmann), the "sector therapy" (F. Deutsch), the "anaclitic therapy" (Margolin and Lindemann), the "diatrophic relationship" (Gitelson), the "working alliance" (Greenson), and the "therapeutic alliance" (Zetzel).

Essentially what these esoteric denominations have in common are: the emphasis on ego psychology and analysis of defenses (A. Freud, Hartmann, Rapaport, Erikson, Lowen- stein, Kris) and on current developmental crises rather than exploration of the unconscious; a more modest view of the healing role of the psychoanalyst; and, historically, a return to some themes brought forward in the early psychoanalytic literature and then forgotten.

Even so, dissatisfaction toward the psychoanalytic movement in toto is mounting, and a "generation gap" is emerging between classical psychoanalysts and young therapists open to eclectic and unorthodox approaches and more attuned to present social realities. While the basic

clinical postulates of psychoanalysis will remain valid in the future, it is difficult to predict the outcome of the theoretical foundations of this movement. At the moment the attempts to graft them on a broader and more relevant context, such as Grinker's "transactional" views, seem the most promising and fruitful.

Hypnosis

Hypnosis, scientifically practiced in the late nineteenth century by the Salpetriere School (Charcot) and by the Nancy School (Liebeault and Bernheim), is at the root of the early psychotherapeutic treatment of neuroses practiced by Freud and Breuer in cases of hysteria in 1893 and 1895. As the psychodynamic school gained momentum, the historical roots of hypnosis, traceable to Mesmer and, further back, to the Greeks and preliterate cultures, were illustrated by some.

It is well known that Freud rejected hypnosis after a few years and that its use for anesthetic and surgical purposes, introduced in the mid-nineteenth century, was soon forgotten, also as a result of the theatrical use of hypnosis. Only in the forties, following some pioneer work by C. Hull *(Hypnosis and Suggestibility,* 1933) was hypnosis scientifically investigated by M. Erickson, L. Mecron, J. Schneck, L. Wolberg, and others. Ry that time considerable experience had been gathered in hypnotherapy and narcoanalysis during

World War II. Eventually the Society for Clinical and Experimental Hypnosis (1949) and later the American Society of Clinical Hypnosis, which publishes *The American Journal of Clinical Hypnosis,* were founded.

In recent years the theories of play acting to please the hypnotist (M. Orne) and of archaic oral-dependent relationship between subject and therapist (M. Gill and M. Brennan) have been postulated. Also the connection between hypnosis and depth and extension of the field of consciousness achieved through the use of particular drugs (LSD 25, mescaline, and others) and the relationship of hypnosis to behavior modifications have been investigated. Despite these developments the future of hypnosis remains vague at this point, although its value in conjunction with psychotherapy is well established.

Client-Centered Therapy

Among the various schools of psychotherapy the only one with a fully American origin was developed by the psychologist Carl Rogers (b. 1902) first in Ohio (1940-1945) and then in Illinois (1945-1950). This school focuses on the genuine, understanding, involved, yet supposedly neutral attitude of the therapist, who continually reflects his feelings toward his client. Historically the lay analyst Otto Rank early in the century advocated the analysis of the therapist's feelings and respect for the patient.

Client-centered therapy appears to have elicited an ambivalent reaction from American psychiatry: on the one hand, psychologists, counselors, and other members of nonmedical groups have mainly used this form of treatment for young and sophisticated clients suffering from problems rather than definite clinical entities (thus nonpatients in the medical sense); on the other hand, Rogers and his pupils have done important research on psychotherapy with the help of purposely designed inventories and tests. In essence this school represents a combination of the humanistic defense of the person and the scientific approach to psychotherapy.

Group Psychotherapy

Group psychotherapy results from the confluence of many trends originally independent from psychiatry. The American inclination toward collective gatherings of different types (intellectual, political, religious) historically appears to be an attempt to overcome the feelings of isolation resulting from the loss of the support provided by each society from which the immigrant groups came. Moreover, in the European societies centuries-old cultural and religious ceremonies contributed to the release of emotions.

In this country great release of feelings was achieved by some religious sects—notably the Christian Science movement in the nineteenth century. With the progress of civilization and concomitant urbanization, as well as

decline of the sources of support provided by traditional values, today's man tends to feel alienated, or "other-directed" in the sense of Ries- man (*The Lonely Crowd,* 1950), and influenced by "groupism" in the sense of Whyte *(The Organization Man,* 1956).

As a result of this situation groups of patients of different kinds were formed by some: "classes" of tuberculous patients by J. Pratt in Roston (1905), lecture classes for mental patients by E. Lazell at St. Elizabeths Hospital in Washington, D.C. (1919) and by T. Burrows and by L. Marsh in the New York City area, the "impromptu theater" by J. Moreno also in New York (already practiced in Vienna early in our century). While these various groups were composed for different reasons and the emotional outlet was only coincidental, later on psychoanalytic concepts tended to prevail in groups formed for psychiatric purposes: mainly, analytic group therapy introduced by L. Wender and P. Schilder, activity groups for disturbed children practiced by S. Slavson at the Jewish Roard of Guardians, and, to a less extent, "psychodrama," which makes use of particular techniques (auxiliary ego, mirror, double, and role reversal), practiced by J. Moreno, all in the New York City area.

Moreno was the first one to attempt to conceptualize his methods by founding the journal *Sociometry: A Journal of Interpersonal Relations* in 1937. However, aside from psychoanalytic notions, only with the advent of K.

Lewin's "field theory" in the thirties (first at Harvard University and then at the University of Michigan in Ann Arbor) were the theoretical foundations of group dynamics able to offer a much needed scientific basis to the field of group psychotherapy. Since then this field has acquired a more stable image with the help of professional meetings and journals, especially *Group Psychotherapy* (1947) and *International Journal of Group Psychotherapy* (1951), founded by the homonymous associations.

As a result of all this, progress has been made in identifying goals, in selecting proper patients, and in structuring the role of the leader in the formation of groups. '' However, some basic issues, such as the conceptual definition of group psychotherapy and the modalities of training for leaders, are still clouded by uncertainty. In recent years the rise of all kinds of new groups (from Alcoholic Anonymous to encounter groups, sensitivity training, and others) has put the professional movement of group psychotherapy on the defensive. Proper historical perspective may be found in the surveys by J. Klapman, R. Dreikurs and R. Corsini, G. Bach and J. Illing, and others.

Family Therapy

Family therapy, scarcely mentioned in the first edition of this work, has become prominent in the last dozen years, to the point of being considered as the treatment of choice by some. For the historian the reason for this rapid

success, over and above the field of psychiatry, has to be found in family therapy's attempt to strengthen an institution that traditionally has contributed a great deal to the prevention and treatment of mental disorders and that is now affected by some basic problems: decrease of family ties, virtual loss of the extended family, and rise of the divorce rate.

As in group psychotherapy, various trends stemming from psychoanalysis and from group dynamics have contributed to the development of family therapy. No one has been more instrumental in fostering the field of family therapy than N. Ackerman (1908-1971), through his many writings (especially *The Psychodynamics of Family Life,* 1958), lectures, courses, and, eventually, formal training at the Family Institute in New York City founded by him in 1960.

In time the early themes of family therapy based on psychoanalytic notions (family secrets, emergence of a scapegoat, and so forth) have been replaced by notions acquired through study of the group dynamics of the family process either at the research level (J. Spiegel, J. Bell, and others) or from the practical perspective (G. Bateson, D. Jackson, and V. Satir of the so-called Palo Alto Group, which has published *Family Process* since 1962; T. Lidz and A. Cornelison of the Yale Group; Boszormenyi-Nagy, J. Minuchin, C. Sager, as well as R. D. Laing in England, and others).

Essentially the emphasis is on the threefold perspective of the patient's dynamics and role, the sociological approach, and the cultural dimension; this is clinically manifested through identification of areas of health and pathology, focus on communicating and sharing, and movement toward the ecological model of community psychiatry (E. Auerswald). All this constitutes a considerable departure from the classic dyadic relationship of orthodox psychoanalysis, in which the family was taken for granted as a solid institution. This image of the family is so altered today in American society to be a cause of concern for many. The historical consideration that the family has remained a landmark in all cultures at all times may help overcome this pessimistic view. Within the limits of psychiatry proper, there is no question that the field of family psychiatry will continue to develop, at the expense not only of individual psychotherapy but also of child and adolescent psychotherapy.

Behavior Therapy

Behavior therapy is so recent that it was not even mentioned in the first edition of this work. In a matter of a few years this school has gained a great deal of interest, if not of acceptance, partially as a result of the caustic criticism of psychoanalytic therapy by some, notably H. Eysenck at the Maudsley Hospital in London.

The foundations of behavior therapy have to be related to the two schools of conditioning (or conditional) learning theory and of reinforcement theory, respectively. The first school is identified with the Russian I. Pavlov (1849-1936), who derived some of his concepts from his fellow countryman I. Sechenov (1829-1905). To a less extent, even the research on "reflexology" by V. Bekhterev (1857-1927) in Leningrad, resulting in the so-called rational therapy—a mixture of medical and environmental regime—is pertinent. Pavlov's notions of conditioning were used in this country first by behaviorists in the twenties, then by animal researchers, and finally by clinicians, notably W. Gantt (b. 1893), who studied under him in Russia and who founded the Pavlovian Laboratory at Johns Hopkins University in 1930 and, more recently, the Pavlovian Society and the *Conditional Reflex and Soviet Psychiatry Journal.* A basic criticism of this movement is the difficulty of translating animal into human behavior, that is, to make the higher nervous activity relevant to clinical issues. The other school of reinforcement theory based on learning, anticipated by E. Thorndike's instrumentalism and by Hull's stimulus-response theory, led to some clinical studies (notably on frustration and aggression by J. Dollard and N. Miller) and to the controversial operant conditioning by the Harvard psychologist B. Skinner.

Behavior therapy, so named by R. Lazarus and H. Eysenck in the late fifties, is especially identified with the work of the psychiatrist J. Wolpe (b. 1915), first at the University of Witwatersrand in South Africa and then at

Temple University in this country. His main tenets, presented in detail in Chapter 43 of this volume, are based on desensitization and reciprocal inhibition, positive and negative reinforcement, aversive conditioning, extinction, and other techniques.

Some reasons for the success of behavior therapy are the dissatisfaction with psychodynamic therapies, its apparent measurability consonant with the English empirical tradition, and, perhaps, the increased status of the psychologist functioning as a therapist. Within the movement of behavior therapy there are considerable internal contrasts between those inclined to emphasize the theoretical assumptions (J. Wolpe) and those inclined to emphasize the empirical applications (R. Lazarus), as well as between the researchers and the practitioners in the psychological profession.

The attitude of most psychiatrists toward this movement is ambiguous: the therapeutic successes are often considered only symptomatic, superficial, and transient; nevertheless, this approach may be useful in treating large numbers of unsophisticated patients, especially in the context of the community mental health movement. In the light of all this, it is difficult to pass judgment on the long- range importance of this school. It is likely, however, that common points—mainly relevance of symptoms, role of the therapist, and the doctor-patient relationship—between the behavioral and psychodynamic schools, rather than areas of disagreement, will be stressed in

the future.

New Areas of Psychotherapy

Psychotherapy of Schizophrenia. Even from the scanty reports of treatment of very disturbed patients carried on during the period of "moral treatment" in the nineteenth century, as well as by other systems at other times, it is clear that psychotherapy of psychoses was at times successful. For a number of years after the advent of psychoanalysis, psychotherapy of psychoses was rejected almost universally (K. Abraham was perhaps the only exception) on the basis that the patient was unable to develop a transference neurosis.

In the forties H. Sullivan illustrated concrete cases of psychotherapy of schizophrenia carried out by him at the Sheppard Pratt Hospital in Towson, Md., on the basis of his interpersonal theory of behavior. While his empirical efforts influenced many in this country and in Europe, his theoretical formulations never gained popularity. Much more accepted was F. Fromm-Reichmann's *Principles of Intensive Psychotherapy* (1950), in which the concept of the "schizophrenogenic mother" was stressed. Ry that time considerable controversy had been elicited by the technique of direct analysis introduced by J. Rosen, first in New York City and then at the Institute for Direct Analysis (founded in 1956 at Temple University in Philadelphia); direct

analysis is similar to the so-called symbolic realization described by M. Sechehaye in Switzerland.

In recent years sound attempts have been made by some—notably S. Arieti—to correlate each technique of treatment of schizophrenia with a particular stage of individual development: for example, lack of maturational development in early childhood (H. Sullivan, J. Rosen, L. Hill) or, conversely, compensatory defenses of the second stage in terms of reestablishing disturbed communications between the patient and his family (G. Bateson, D. Jackson, T. Lidz, L. Wynne).

Historically, similar to the neuroses, the emphasis appears to have shifted from individual treatment to the treatment of the patient in the context of his family and community. Thus far, psychotherapy of psychoses has tended to be carried on by a few therapists endowed with strong personality and keen intuition. The need in the future is for methodologically sound research.

Brief Psychotherapy. The expression "brief psychotherapy" has appeared in the literature in recent years, probably as a result of the need to offer treatment to the large number of patients brought forward by the community mental health movement (P. Castelnuovo-Tedesco, 1962). While the focus on this approach is new, its use in some cases goes back to Freud

himself (particularly in the famous treatment of the conductor Bruno Walter) and to some of the early psychoanalysts. Alfred Adler practiced short-term therapy for many low-income patients in whom he had considerable interest; S. Ferenczi and O. Rank advocated a limited number of sessions to avoid unnecessary dependency and regression in the patient in their volume *The Development of Psychoanalysis* (1923); during World War II brief psychotherapy for the treatment of combat neuroses was widely used, as reported by R. Grinker and A. Kardiner; finally shortening of psychotherapy was advocated by F. Alexander and T. French in *Psychoanalytic Therapy* (1946) on the basis of their research at the Chicago Institute for Psychoanalysis.

In spite of all this, psychoanalytic therapy has tended to be taught and practiced from the perspective of long-term treatment. What is new is the emphasis by many today on considering brief psychotherapy as the treatment of choice on the basis of diagnostic considerations and practical aspects (cost, waiting list, availability of staff, community attitudes, and so forth). Clearly, brief psychotherapy focuses on crises, traumata, emergencies, and, in general, acute decompensations, rather than on personality disturbances, and its success is partly related to the patient's and the therapist's expectations.

The main criticism of brief psychotherapy centers on its lack of a theoretical dimension, as it is the result of the amalgamation of all kinds of

practices derived from systems as diverse as psychoanalysis and behavior therapy (as illustrated in the recent book by L. Small, *The Briefer Psychotherapies).* This is certainly a considerable weakness, though certainly not unique in the field of psychotherapy, in the light of the unproven assumptions of longterm psychoanalytic therapy. Nevertheless, in the context of the community mental health movement, brief psychotherapy will foreseeably acquire importance, necessitating proper theoretical formulations and methods of teaching.

Psychotherapy according to Interpersonal Theory, Cognitive and Volitional School, Communication Theory, and Transactional Analysis. Common to all these various trends—most of them already mentioned somewhere in this chapter—are their American origin (though not devoid of indirect European influences) under the impact of the melioristic approach of sociology in this country, their defense of the individual against dehumanizing forces, and their modest view of the role of the therapist as a mediator or interpreter in contrast to the omnipotent image of the psychoanalytic tradition. Moreover, their tenets have been illustrated by their various originators in a rather unsystematic way without the support of rigid organizations, justifying calling them trends rather than schools.

The *interpersonal theory* of behavior is mainly represented by K. Horney, H. Sullivan, and E. Fromm, Horney, influenced by character analysis

(H. Schulz-Henke and W. Reich) and the American concept of the "self" (G. Mead), in a number of popular books illustrated the clinical implications of self, self-image and relationship of the self to others on the basis of the experience gathered at the Psychoanalytic Institute in Chicago and then at her own American Institute of Psychoanalysis in New York City. While these notions have been relevant to American psychiatry, especially in the treatment of asymptomatic eharacterological patterns, her attempt to replace didactic analysis with self-analysis has been rejected.

Sullivan's lasting contribution to therapy, originated with the above-mentioned treatment of schizophrenic patients, lays in his emphasis on the role of the patient as "participant-observer" and the patient-staff interaction in the mental hospital, while his nomenclature of psychiatric conditions is now almost completely forgotten.

Fromm's numerous volumes, primarily addressed to the intellectual and progressive elite, stem from an attempt to combine Marx's notions (mainly the pathos of the "alienated" man in today's collective society) with psychoanalytic insight. Though very appealing, their relevance for psychiatry is quite limited.

The main thrust of the *cognitive and volitional school,* a new trend represented by psychiatrists and psychologists (A. Beck, J. Barnett, J.

Bemporad, and others), has been clearly stated by S. Arieti, its originator, in Chapter 40C of this volume: "A stress on cognition and volition docs not imply that affects are not major agents in human conflicts and in conscious and unconscious motivation. It implies, however, that at a human level all feelings except the most primitive are consequent to meaning or choice. In their turn they generate new meanings and choice." In essence primary consideration is given here to the cognitive dimension in its relation both to conflict and creativity in the light of its unique importance for the human condition.

The *communication theory* of behavior, influenced by philosophical analysis of language, linguistics, and notions of physical field and psychological field theory, has focused attention on the process of verbal communication through which psychotherapy occurs. General systems theory, mainly through the efforts of R. Grinker, has been particularly interested in the transactional perspective.

Finally Eric Berne (1910-1970) has described, in his popular and successful book *Games People Play,* his system of *transactional analysis* in which exteropsychic, neopsychic, and archaeopsychic ego states (colloquially called parent, adult, and child) are combined in the different forms of basic human interactions.

Psychotherapeutic Borderlines:
Sensitivity Training, Encounter, and Marathon Groups

The various movements listed in this section are quite recent and all of American origin. Their rapid success in some quarters, mainly outside the realm of psychiatry proper, appears to derive from the increasing isolation and alienation felt by many; paradoxically these feelings are reinforced by the close and impervious atmosphere of the individual psychotherapeutic relationship.

Historically the psychological aspects of the behavior of crowds were studied by French sociologists at the beginning of our century, followed by the development of social psychology and, in the forties, by forms of collective therapy. The founding of sensitivity training is attributed to the importance given to group self-evaluation during sessions for training of community leaders dealing with racial problems by three educational and social psychologists, L. Bradford, B. Lippitt, and K. Berne in 1946. Out of this initial effort, supported by the Gould Academy in Bethel, Maine, resulted the work of the National Training Laboratories. Eventually in the fifties the emphasis shifted toward individual self-actualization and in the sixties toward antiintellectual and nonconforming techniques.

A variety of issues have risen in connection with this movement: the transitional nature of their methods based on the "here and now"; their appeal mainly to sophisticated people (not "patients") of the East and West Coast; the call for "honesty" on the part of every participant and leader (and

the consequent ambiguous role of the leader, perceived as a peer but different); the possibility of bringing underlying psychopathology to the surface through these sessions; and consequently the ethical aspect of the leader's responsibility.

Similar issues have been raised in regard to nonverbal techniques emphasizing the unity of body and mind and grouped under the term of Gestalt therapy. Common to all of them (initiated by the neo-Reiehian A. Lowen with his bioenergetie group therapy) is the postulate that release of tension, which expresses itself through emotional disturbances or peculiarities of muscular posture, can be achieved just as successfully through physical activities as through verbal psychotherapy. The techniques developed at the Esalen Institute in California since 1964 by F. Peris, B. Schutz, and B. Gunther center around the manifestations of body language in a variety of ways.

For the historian it is too early to pass judgment on the significance of this movement, since it is not clear at this point whether it constitutes a momentary fad or the beginning of a new orientation in psychotherapy. It is a fact that systems of healing of classical Greece and of Eastern civilizations took into consideration the body as well as the mind, as pointed out in some publications (such as *Asian Psychology,* edited by G. Murphy and L. Murphy; *Psychotherapy East and West,* by A. Watts; and a number of monographs on

Zen Buddhism). Those therapeutic methods, however, represented an expression of their own culture, while the methods described in this section appear to be isolated attempts to counteract the dehumanizing trends of our civilization.

Research in Psychotherapy

Reference to research in regard to therapy, including psychotherapy, has already been made in some scattered passages in this chapter. However, the matter deserves more consideration in view of the importance of psychotherapy.

Two points stand out, in some way related to each other. In the first place psychiatrists appear to have been unconcerned traditionally with the careful assessment of the results and follow-up of psychotherapy. This attitude may have been due to a number of reasons: the discouraging number of variables intervening in the psychotherapeutic process; the lack of adequate training in research methodology for medical students; the exclusion of psychologists and other research-oriented nonmedical professionals from psychoanalytic associations; the adherence of each therapist to a particular school, which interferes with the objectivity necessary for research; the empirical attitude of the American mentality, coupled with a humanistic defense of the individual obviously opposed to the

quantifying orientation of research; and finally an exaggerated concern about the confidentiality of psychotherapeutic scenes.

In the second place, partly as a result of this situation, partly as an attempt to show their vital role in the field of psychotherapy, psychologists have taken most of the initiatives in regard to research on psychotherapy. This is substantiated by a perusal of the most important publications in this field such as *Methods and Research in Psychotherapy* edited by L. Gottschalk and H. Auerbach, *Research in Psychotherapy* by J. Meltzoff and M. Kornreich, preceded by the monographs *Research in Psychotherapy* (1959, 1962) published by the American Psychological Association.

Since most psychiatrists appear to disregard psychological literature, the introductory statement to a thorough review of the entire field of research in psychotherapy by H. Strupp and A. Bergin seems justified: "Thus far, research in psychotherapy has failed to make a deep impact on practice and technique." The few issues dedicated to this topic by the *American Journal of Psychotherapy*, the small monograph *Psychotherapy and the Dual Research Tradition* (1969) by the Group for the Advancement of Psychiatry, and the above-mentioned *Psychiatry as a Behavioral Science* edited by D. Hamburg do not essentially alter this statement.

This state of things, which accurately portrays the present situation,

may, however, change in the future in connection with some developments: the decrease of the omnipotent image of the therapist and of the charismatic role of therapy; the influence of behavior models of psychotherapy conducive to measurement; and the overall political and social situation, which calls for a more thorough justification of the use of public funds in the field of mental health, even in psychotherapy.

Milieu Therapy

The influence of the environment in the care and treatment of the mentally ill in any institutional setting may have been overlooked, but it has certainly been present from early times on. Evidence of the importance of environmental factors can be easily found in the early psychiatric literature at the beginning of the nineteenth century and then in the period of moral treatment. Eventually, with the prevalence of large mental hospitals in the latter part of the century, the environment became more custodial and impersonal.

The advent of the psychodynamic approach did not alter this situation as the focus came to be on neurotic, nonhospitalized patients. The same situation persisted with the introduction of shock therapies in the late thirties. Even the interpersonal theories of behavior that developed in this country, while reducing the omnipotent role of the therapist to more modest

proportions, did not modify the essentially obscure role of the environment.

A substantial change, in the sense of the environment itself becoming the focus of attention, took place only in the mid-fifties in connection with some important studies: notably, *The Therapeutic Community* (1953) by M. Jones in England and *The Mental Hospital* (1954) by Stanton and Schwartz, based on their experience at Chesnut Lodge, under the influence of F. Fromm-Reichmann, H. Sullivan, W. Menninger, and others.

Since then many studies carried on in mental hospitals have attempted to define the characteristics of the physical setting, roles and role relationships, authority and control, communication and culture in general. Much effort has been made to prove the underlying assumption that a stable environment, in which the operating forces are known, contributes to the reinforcement of the ego of the patient.

This has resulted in attempts at defining such forces in terms of conflict-free areas of the ego and adaptation (H. Hartmann), in terms of clarification and learning of roles (T. Parsons, G. Mead), on the basis of the notion of the field of forces (K. Lewin's "lifespace"), and from the overall perspective of Western democratic society. Up until now the best attempt to conceptualize the therapeutic areas of the environment remains *Ego and Milieu Therapy* by J. Cumming and E. Cumming. It is likely that in the future the therapeutic

milieu will increasingly be considered as an open system from the viewpoint of the general systems theory and will be concretely affected by the movement of community psychiatry.

Psychiatric Education

From the broad perspective of systems of healing and attitudes toward the mentally ill in preliterate societies, it is clear that methods of apprenticeship for medicine men have been in use from earliest times (for instance, in the training of shamans in many cultures). Among their common characteristics were the "call" of the candidate through dreams, a period of isolation under the close guidance of an experienced healer, and finally the return to the community, which had definite expectations of supernatural powers in the new medicine man, to be manifested through rigidly established rituals. All this, of course, bears resemblance to the training of today's psychotherapists.

However, the awareness of these similarities is only recent. Traditionally psychiatric education has been traced back to the early nineteenth century, when young physicians underwent a highly personalized, yet unstructured, system of apprenticeship around moral treatment in the early mental hospitals in the Western countries. The decline of such a philosophy of treatment late in the century coincided with the rise of

"scientific" psychiatry, mainly in German universities, based on the belief in the ultimate neuropathological etiology of mental disorders.

In this country, instead, psychiatric training (as well as research) continued to take place very empirically in mental hospitals, thus justifying the famous critical address given by the neurologist W. S. Mitchell in 1894 at the occasion of the fiftieth anniversary of the American Psychiatric Association. Eventually a new spirit conducive to better training was introduced at the beginning of this century at the Worcester State Hospital by A. Meyer (who first developed there his "life chart" of the individual development of the patient). Later on the Henry Phipps Clinic at Johns Hopkins University also opened under Meyer's leadership, following the model of the Kaiser Wilhelm Institute for Psychiatry in Munich, the so-called Kraepelin Institute.

Since then much has happened in the field of psychiatric training in this country. The American Board of Psychiatry was established in 1934 to set up standards of training and certify physicians in the specialty of psychiatry." Around the same period teaching in psychiatry came to be organized, both at the undergraduate and at the postgraduate levels, in a number of hospitals and outpatient facilities with the help of private foundations (especially the Commonwealth Fund and the Rockefeller Foundation) and a few interested professionals (such as A. Gregg, F. Ebaugh, and C. Rymer, authors of

Psychiatry in Medical Education, and H. Witmer, who published *Teaching Psychotherapeutic Medicine).*

World War II, by emphasizing the great need for psychiatry, led to a vast program of psychiatric training by the Veterans' Administration. From the early fifties on, such a program has been undertaken almost exclusively by the National Institute of Mental Health through its division of training and manpower. By the time the First Conference on Psychiatric Education was held at Cornell University in 1951, the report on medical education sponsored by the Group for the Advancement of Psychiatry (1948) had identified the main areas of training as personality development, unconscious motivations, and dynamic comprehension of the individual case; a program of "comprehensive medicine" inclusive of psychological development and case work principles was developed in some medical schools (Western Reserve, Colorado, Pennsylvania, Tennessee, and Harvard); and departments of "behavioral sciences" and courses in "human ecology" were offered by others (Syracuse and North Carolina, respectively).

In the fifties, with the rise of psychoanalysis, the issue of psychoanalytic training as an essential aspect of the training of the psychiatrist, to be carried on independently in psychoanalytic institutes or in the framework of medical schools, became outstanding (for example, in the 1954 symposium in the *International Journal of Psychoanalysis* and in F. Alexander's *Psychoanalysis*

and Psychotherapy). Despite the many controversies, this issue is still unsettled today, but it has been essentially bypassed by the events related to the decline of the psychoanalytic movement and the parallel rise of the community mental health movement. Instead, what has remained of the psychoanalytic influence has been the system of supervision, defined in its threefold aspect of patient-centered, process-centered, and trainee-centered, especially in the well- known study by R. Ekstein and R. Wallerstein.

In the last two decades most of psychiatric training has taken place with the support of the federal government: the original program of NIMH began with a little more than 200 grants annually and now is in the realm of 10,000. This has had, on the one hand, the advantage of fostering a certain degree of homogeneity and of maintaining high standards; on the other hand, it has tended to favor large and well-known centers located in urban areas, thus interfering with the aim of making psychiatry available even in less populated areas of the country.

Serious efforts have been made toward offering a comprehensive type of training, including experience in state institutions, outpatient clinics, special facilities (for example, for children or for delinquents), and presenting a manifold philosophical orientation (genetic, organicistic, psychodynamic, and epidemiological) and various therapeutic approaches (chemotherapy, individual as well as group and family therapy, and others). In view of the

vastness of each new field of psychiatry, such an ambitious program can be realistically carried on in very few places.

Likewise, limited success has characterized the various efforts to influence practicing physicians to take a more progressive attitude toward psychiatry and emotional disturbances in general, either at the undergraduate level or at the postgraduate level, with the help of federally supported seminars. In spite of the widespread belief of the pervasive influence of mental on physical pathology in many patients (as represented in the appealing volume *Man, Mind and Medicine,* edited by the distinguished surgeon, Oliver Cope), only slow gains toward the acceptance of psychiatry have been made thus far among the already established professionals. The young physicians recently graduated from medical schools seem to be more open-minded toward psychiatry, even in regard to some new controversial therapeutic group approaches.

Recent developments in the field of psychiatric education include the tendency toward specialization in psychiatry during training in medical school and toward training in a subspecialty of psychiatry during the residency period (initiated at Yale); the concern for providing adequate training in community psychiatry, especially in regard to urban problems; the controversies related to discontinuing the internship before the psychiatric residency (as a result of the Mill's Citizen's Commission on Graduate Medical

Education in 1966); finally the programs for continuing education for psychiatrists (mainly under the leadership of the late W. Earley) and the self-assessment project sponsored by the American Psychiatric Association

The future of psychiatric manpower remains far from bright although between 10 to 20 percent of medical students decide now to embrace psychiatry, which has become the third largest specialty. Also a cause of concern is the shortage of psychiatrists actively involved in research, in spite of the efforts made by the National Institute of Mental Health.

In recent years it has become apparent that many young psychiatrists are interested in humanistic medicine, that is, in the comprehensive approach to patients of any social class and their families and communities. Unfortunately the training of the physician and, subsequently, of the psychiatrist is so long as to discourage a number of young men from entering this field. This has given further impetus to the proposal—advanced by L. Kubie years ago—to establish a doctorate in medical psychology. In view of the traditional determination of professional psychiatric and psychoanalytic organizations to limit training in psychotherapy to physicians, this has remained a very debatable issue up until now. But efforts in this direction continue to be made, as evidenced by the recently published book *New Horizons for Psychotherapy, Autonomy as a Profession,* edited by R. Holt.

The future of psychiatric education, though promising in terms of innovations and increased flexibility, has recently been clouded by the financial restrictions applied to the budget of the National Institute of Mental Health. This may result in a broader support of training at the state and local levels, whose impact in psychiatry is difficult to assess at the present moment.

American Psychiatry in the Context of Psychiatry in Other Countries

Within the limits of this chapter it is possible only to present some general trends concerning the interplay of psychiatry in the United States and in other countries, the reciprocal influence of models of the mind and therapeutic methods, and the foreseeable developments in the future. Since no comprehensive publication on psychiatry throughout the world exists at the moment, the following remarks are the result of a broad perusal of pertinent literature scattered in many publications. The lack of a comprehensive view on this subject here is partially compensated for by the various references to theoretical and practical aspects of psychiatry in other countries made in other sections of this chapter.

From the overall historical perspective the relevance of discussing psychiatry abroad for a better comprehension of American psychiatry is unquestionable, at least on three grounds: (1) the manyfold cultural traditions from Europe, Africa, and, to a less extent, other continents that are

the basis of American society; (2) the persistent interest that this country has had in supporting scientific and humanitarian projects abroad, especially in Western countries damaged by World War II, some countries of Latin America, and newly developing Afro-Asian areas; (3) the convergence of practical methods of healing carried on in underdeveloped countries and approaches to community mental health recently introduced in this country.

Even a succinct discussion of the above points calls, however, for some preliminary considerations. The methodological perspective in the comprehension of other countries has undergone a tremendous change in the course of the century and a half of development of modern psychiatry. During a good part of the nineteenth century American psychiatry tended to follow European psychiatry, first in regard to the practical aspects of moral treatment, then in regard to the clinical orientation of the French school and the theoretical research on neuropathology of German universities. The acceptance of the Freudian message, prepared for by the emphasis on environmental factors in the etiology of emotional disturbances brought forward by various trends (progressivism, behaviorism, Meyer's psychobiology), led to the tendency to assess mental pathology and attitudes toward the mentally ill in our country from the almost exclusive perspective of psychoanalysis up until recently. Finally, parallel to the spread of the community mental health movement and to the progress in communication systems (easy transportation, international meetings, speedy translations),

approaches to mental illness and its treatment carried on in other countries are becoming more known even in the United States.

Concomitant with this has been a better definition of the three growing fields of: (1) *trans*cultural psychiatry, in which scientific observation is extended to non-Westem practices; (2) *cross*-cultural psychiatry, which focuses on comparative and contrasting dimensions of psychiatry in various countries; (3) *international* psychiatry, which emphasizes teaching, training, and, in general, organizational aspects in the different political entities of the world. These three fields overlap to a certain extent, and, furthermore, a thorough discussion of the first two will be offered in other sections of this handbook. Consequently here the presentation will be limited mainly to the developmental aspects of international psychiatry, which is not covered elsewhere.

In spite of the tendency toward the spread of Western practices all over the world, resulting in the transformation of "pure" cultures into cultures at different levels of acculturation, for didactic purposes the following discussion is divided into: (1) countries of the Western tradition, that is, mainly Europe (including Russia), Canada, Australia, South Africa, Israel, Latin America; (2) countries of the Far Eastern tradition, that is, India, Japan, China, and some others; and (3) international psychiatry. The developments of psychiatry in these various countries will be presented essentially in their

relevance to American psychiatry.

Psychiatry in Countries of the Western Tradition

On the one hand, in view of the different ethnic, cultural, economic, and political aspects of the many countries of the Western tradition, it is impossible to present the developments of psychiatry in a compact and unitary form. On the other hand, the interchange of ideas and people among these countries has been so great that it is impossible to conceive of the developments of psychiatry in each one of them independently from the others. Yet some general characteristics have emerged in most of these countries, and the discussion will center around them.

To begin with, a few main aspects stand out clearly on the basis of some important publications by G. Allport, H. Ellenberger, L. Beliak, and a few others. There are many similarities between British and American trends, at variance with continental trends: the empirical tradition (derived from Locke), which emphasizes environmental forces, social interaction, and optimistic expectations; a positivistic approach to the formulation of "brain models"; the study of traits, attitudes, and motivation rather than the total personality; the tendency to consider mental disturbances as "reactions" rather than symptoms; the inclination toward pragmatic use of therapeutic methods developed somewhere else regardless of theoretical speculations;

finally the interest in experimentally testing the above methods by interdisciplinary teams of scientists. The main difference between Great Britain and the United States consists, of course, in the uniformity of the ethnic and cultural scene of the former vis-a-vis the racial and social pluralism of the latter, with definite repercussions on psychiatry. This is reflected in the mobility of professionals in psychiatry and collateral fields, leading to rapid spread of ideas, homogeneity in clinical practices, and eclectic approaches.

In contrast, Continental Europe, with the notable exception of Russia and, to a less extent, of other communist countries, has been characterized by the rational tradition (derived from Leibnitz and Kant), which has resulted in a more philosophical view of mental life; the persistent concern with the "whole man," which stems from the Greek tradition and which is somehow responsible for a humanistic (and humanitarian) orientation; a pessimistic orientation toward life in general, probably influenced by the long-term experience of wars, migrations, famines, exterminations, and other horrible events, as evidenced by Freud's preoccupation with death and by the dramatic aspects of the existentialist movement; a concern with the individual rather than with the social dimensions of the personality; a preoccupation with symptomatology and diagnostic categories at the expense of therapeutic efforts; a succession of brilliant "discoveries," from psychoanalysis to shock treatment, psychopharmacology, and community

psychiatry, by isolated scientists; finally a tendency toward fragmentation of psychiatric theory and practices into definite "schools," each one led by an academician and followed by his pupils (and represented by special journals and publications), quite often bitterly opposed to each other.

In general, it is very difficult to follow the developments connected with the interrelationship of American and European psychiatry. Regardless of differences due to language barriers, personality patterns, and social customs, the traditional influence of European on American psychiatry underwent a significant change after World War II; such an influence persisted in regard to discoveries and introduction of new therapeutic systems (for example, in community psychiatry), but was paralleled by an opposite influence of American on European psychiatry, especially in the fields of psychoanalysis, child psychiatry, research, and training.

Historically it would appear that certain periods have been characterized by a common psychiatric approach in Europe and the United States: (i) moral treatment in the early nineteenth century; (2) organicistic philosophy in the late nineteenth century; (3) psychoanalytic influence in the early twentieth century, followed by an interest in shock treatment later on; (4) psychopharmaeologi- cal approach and methods of community psychiatry in the last two decades. For the purpose of this chapter the discussion will be necessarily limited to this last point, as advances in chemotherapy have

already been discussed above, also from the international perspective.

Interest in community psychiatry began to be noticeable in this country in the mid-fifties, following the important publications in England on the "open-door policy" in mental hospitals, on day hospitals (J. Bierer), and on the therapeutic community (M. Jones), as well as the successful program of public mental health introduced in Amsterdam by A. Que- rido.

Shortly thereafter, the volume *Impressions of European Psychiatry* (edited by W. Barton, *et al.)* appeared in 1959 under the sponsorship of the American Psychiatric Association. It then became evident what the main positive aspects of European psychiatry consisted of: a better reciprocal respect between patients and staff in institutions, probably because of the humanitarian tradition, systems of education, and division into rigid class systems; a more supportive role by physicians (paternal), by nurses, at times religious (maternal), and by community resources of all types (this latter related to the social stability of the population), resulting in better systems of communication, involvement with families, partial hospitalization, and follow-up; a flexible therapeutic approach, based on chemotherapy and short-term psychotherapy, and carried on by a dedicated staff more interested in their professional vocation than in financial rewards. On the negative side were the uneven and loose systems of training, the lack of systematic support for research even to dedicated scientists, the resistance of professionals to

work in interdisciplinary teams (especially in areas such as child psychiatry where this approach is most valid), the dependence of psychiatry on neurology in some Latin countries, the tendency to centralize the decision-making process in psychiatry (be this service, training, or research) on a few people.

Interesting enough from the historical perspective is the fact that European psychiatry, which appeared to be backward when seen from the American psychoanalytic viewpoint of the fifties, was seen as advanced from the viewpoint of community psychiatry of the sixties. Somewhat related to a more tolerant attitude toward the mentally ill on the part of society, which is basic to community psychiatry, is the pervasive European belief that mental illness is *occurring to* an individual rather than being *synonymous with* him (that is, a patient "has" a schizophrenic illness, but he is not "a schizophrenic").

In *Great Britain* the brilliant psychiatric tradition, initiated with the "moral treatment" and the movement of "no restraint" in the early nineteenth century, was later influenced by the evolutionary concepts of C. Darwin, T. Huxley, and H. Jackson. At the beginning of this century, under the impact of Meyer's psychobiology and Freud's notions, psychoanalysis received great impetus there, mainly through the work of E. Jones. Eventually a good number of psychoanalysts preferred to accept the concepts advanced by M.

Klein and even to follow ideas put forward by C. Jung. The trend of organicistie psychiatry has remained very strong, however, in line with the excellent neurological tradition. Training and research are mainly carried on at the Tavistock Institute of Human Relations and at the University of London Institute of Psychiatry, linked to Bethlem Royal Hospital and Maudsley Hospital, while the most important periodical is the *British Journal of Psychiatry* (which superseded the *Journal of Mental Science).* Many of the 3,350 practicing psychiatrists hold the Diploma in Psychological Medicine and gather around the Royal Medico-Psychological Association, founded in 1841. Among the most prominent psychiatrists are (or have been) D. Henderson, D. Hill, J. Bowlby, E. Miller, A. Lewis, D. Winnicott, W. Fairbain, W. Sargant, D. Leigh, J. Howells, and G. Carstairs. Since 1930, when the Mental Health Act was passed, the social dimension has continually gained importance in psychiatry: in 1948 the National Mental Health Service Act placed the care and treatment of the mentally ill under the Ministry of Health on a regional basis; the Mental Health Act of 1959 removed any legal distinction between patients in psychiatric and in general hospitals. The great majority of psychiatrists work in the context of social medicine and private practice is very limited.

In *France* the pioneering work of Pinel was followed by his favored pupil Esquirol and by many others mainly interested in the clarification of clinical symptoms, in the connection with neurology and in legal- psychiatric

matters in the mid-nineteenth century. Later on the advances made in neurophysiology (C. Bernard), psychopathology (T. Ribot), experimental psychology (A. Binet), and social psychology (E. Durkheim and others) were overshadowed by the clinical application of hypnosis to neurotic disorders by the school of Salpetriere in Paris (J. M. Charcot) and by the rival school of Nancy (H. Bernheim and A. Liebeault), both of which influenced Freud directly as well as P. Janet (1859-1947). Through Janet and some of his early disciples the psychoanalytic movement developed on a limited scale, also with the support (in contrast to the belief of many) of some progressive Catholic quarters. Aside from some psychotherapeutic innovations (such as the technique of "directed daydream" by R. Desoille) the most important event has been the secession from the Psychoanalytic Society of Paris by the French Psychoanalytic Society, led by D. Lagache and J. Lacan; the latter is the author of a famous paper (1953) in which he identified the structure of the unconscious with the structure of the language. Another important group of psychiatrists has centered around the journal *Evolution Psychiatrique,* mainly dominated by F. Minkowsky, a pioneer in the field of phenomenology (represented by M. Merleau-Ponty) and not immune from existentialist influences (J.-P. Sartre). In recent years the two psychiatrists J. Delay and H. Ey, both authors of many publications aiming at the integration of organic and dynamic concepts, have acquired prominence. Recognition has also been given to projects in community psychiatry (especially in the thirteenth

arrondissement in Paris). The new trend of structuralism—mainly represented by the anthropologist C. Levi-Strauss and the philosopher M. Foucault (the latter is the author of an important historical study of psychiatry in the age of the Enlightenment)—may also influence psychiatry considerably. Finally mention should be made of the traditional international role played by France, which has contributed to the communication of ideas; in Paris were held both the First International Congress of Child Psychiatry (1937) and the First World Congress of Psychiatry (1950).

Belgium, the country where family care of the mentally ill was continued uninterruptedly at Gheel from the thirteenth century to the present, has essentially followed the French tradition. At the Catholic University of Louvain, where psychology was initiated by Cardinal Mercier, efforts to combine psychoanalysis with a spiritualistic conception of man were made by A. Michotte and J. Nuttin. The *Netherlands,* where J. Wier, the sixteenth-century pioneer of modern psychiatry was born, has lately become known for the important school of phenomenology (J. Buytendijk, H. Van den Berg, H. Rümke, and others) and for advancements in community psychiatry (A. Querido).

In *Germany* psychiatry appears divided into many schools, historically explainable on the basis of the political and academic independence of each region. The controversy between the "mentalists" and the "somatists" in the

early nineteenth century resulted in the predominance of the latter, represented by W. Griesinger and later by the school of anatomopathology and histopathology (C. Wernicke, T. Meynert, O. Vogt, and others). Early in this century, preceded by the clinical contributions of E. Hecker and K. Kahlbaum, E. Kraepelin established the fundamental dicot- omy of manic-depressive psychosis versus dementia praecox, which influenced nosology everywhere. It was followed by the constitutional school of personality of E. Kretschmer and by the important trend of genetic psychiatry, mainly represented by E. Rudin and his pupil, F. Kallmann; the latter was active for many years at the New York Psychiatric Institute. It is regrettable that in Germany some adherents to genetic psychiatry attempted to offer scicntific justification for the Nazi persecution of the Jews and the alleged superiority of the Aryan race. In the thirties for a few years the Berlin Psychoanalytic Institute, where didactic analysis was first introduced, acquired prestige. After World War II the various psychiatric trends have all been influenced by the existentialist movement, anticipated by the philosophers Husserl and Heidegger: the clinical contributions by H. Griihle, V. Gebsattel, V. Weizsacker, K. Kolle, as well as the so-called neopsychoanalytic movement of H. Schultz-Henke, the current centered around the journal *Psyche* (edited by A. Mitscherlich), the yearly "Lindauer Psychotherapeutic Week" organized by Speer and others. Mention should also be made of J. Schultz-Henke's "autogenic training," which combined Western and Eastern healing practices,

the contributions to ethology by K. Lorenz and others (N. Tinbergen, C. Schiller, H. Hass), and the recent studies dealing with sociological (including Marxist) aspects of psychology, preceded by the pioneering work by T. Adorno in this country and then in Germany (especially his study on the authoritarian personality). Valuable historical studies on psychiatry have also appeared there.

In *Austria* basic concepts of mental hygiene anticipating psychodynamics advanced by E. von Feuchtcrslebcn (*Textbook of Medical Psychology*, 1845) and, later on, studies by the organicistic school (T. Meyncrt, R. Krafft- Ebing) received impetus through the renown of the medical school of Vienna and the extension of the Austrian empire. For the past two decades or so the developments of Freud's ideas and of the psychoanalytic movement have been the subject of many studies in the United States. In Austria, however, Freud's role remained quite limited among his contemporaries, when compared with the success achieved by the Nobel Prize winner Wagner- Jauregg, discoverer of malaria therapy (1917) and, later on, by M. Sakel who introduced insulin therapy in the thirties. Almost all of Freud's pupils from Austria (as well as the sympathizer P. Sehilder, whose studies on the body image and on clinical applications of psychoanalysis have become largely known in this country) emigrated to the United States, with the exception of A. Aichhom, who did pioneering work on the psychoanalytic treatment of juvenile delinquents. In recent years, aside from academic

psychiatry (mainly represented by A. Stransky and H. Hoff), recognition has been accorded to logotherapy (V. Frankl) " and so-called personalistic psychoanalysis (I. Caruso, W. Dain), which emphasizes values and the purpose of life rather than gratification of instincts. '

Switzerland has gained an important place in the development of modern psychiatry, probably owing to its geographical location, traditional neutrality, and multilingual background. In Geneva psychology was cultivated at the Institut Rousseau in succession by T. Flournay, E. Claparede, and J. Piaget (whose studies on the development of the child have become universally known and have increasingly been compared with psychoanalysis). Except for the method of "sleep therapy" introduced by J. Klaesi in Bern in 1922, psychiatry, instead, has traditionally flourished in Zurich, mainly at the mental hospital of Burghholzli, directed in succession by A. Forel, E. Bleuler (who coined the term "schizophrenia"), " and then M. Bleuler. There A. Meyer received his first psychiatric training before moving to this country; the clinical application of psychoanalysis was first introduced by C. Jung (who wrote his famous works on dementia praecox and word associations early in this century); and H. Rorschach developed his test that soon became known the world over. Aside from Jung's followers such as C. Meier, C. Kereny, and others, gathered around the Jung Institute in Zurich and the so-called Eranos meetings in Ascona, worth remembering are the names of the psychoanalysts R. De Saussure, C. Baudouin, O. Pfister, A. Maeder, E.

Oberholzer (who moved to New York City, where he introduced the Rorschach test in the twenties), and H. Zulliger. In recent years existential analysis—mainly represented by L. Binswanger, M. Boss, G. Bally and a few others, all originally influenced by psychoanalysis—has acquired momentum. Aside from biological studies relevant to psychosomatic medicine and psychodynamics (R. Brun, A. Portmann) and eharaeterological studies (L. Klages, L. Szondi), two main trends have emerged in Switzerland: child psychiatry, mainly represented by A. Repond, M. Tramer, L. Bovet, J. Lutz, and H. Hanselmann (who initiated the movement of "Heilpiidogogik" on therapeutic education), and known through the international journal *Acta Paedopsychiatrica;* and the psychotherapeutic treatment of schizophrenia, which, related to the pioneering contributions by C. Jung, E. Bleuler, and A. Storch, has been applied first by M. Seehe- haye with her technique of "symbolic realization" and then by C. Müller in Bern and by the Italian-born G. Benedetti in Basel. Finally mention should be made of the outstanding contributions made by some chemical companies of Basel to the development of psychopharmacology and of the role played by Switzerland in sponsoring international meetings (notably, the First International Congress on Therapeutic Education in 1939 and the Second World Congress of Psychiatry in 1957, both held in Zurich).

In *Scandinavian countries* psychiatry has been dependent on the German tradition up to World War II and on the English tradition thereafter.

The psychodynamic influence has been limited; it is important mainly at the Erica Foundation for Child Guidance in Stockholm and at the Therapeia Foundation recently established in Helsinki by the Swiss-trained M. Siirala. In view of the stability of the social situation and the long-term absence of great military conflicts, research on hereditary factors in mental illness has received a great deal of attention (T. Sjogran, G. Langfeldt) in the context of a strongly supported organicistic framework in psychiatry, as evidenced by the studies published in the important journal *Acta Psychiatrica et Neurologica.* The broad-minded social legislation enacted in Scandinavian countries for some time has brought about successful developments in community mental health.

Italy, Spain, and Portugal are presented together here because of close ethnic, religious, and cultural affinities that justifiably can be extended to psychiatry. In these countries care of the mentally ill has had an illustrious, centuries-old tradition, psychiatry has been predominantly organicistic and dependent on neurology, and psvchodynamics has been opposed by the Fascist and Franchist political regimes on various grounds. In *Italy* the pioneering reform in the treatment of mental patients introduced by V. Chiarugi in Florence at the end of the eighteenth century was soon forgotten. Instead more recognition was accorded to the histoneurological studies by the Nobel Prize winner C. Golgi and the pathographic studies by C. Lombroso —the founder of criminal anthropology—early in this century. At the

University of Rome S. De Sanctis's notions on child psychosis (*Dementia praecocissima,* 1906) were soon overlooked, while electric shock introduced by U. Cerletti and L. Bini in the late thirties was applied everywhere. Recently interest in psychoanalysis and existentialism has increased.

Spain, considered "the cradle of psychiatry" because of the foundation of some pioneering mental hospitals in the fifteenth century, later on went through a long period of decline. Only at the beginning of this century ample recognition was granted to the studies on histopathology of the nervous system by Ramon y Cajal and his school. In recent years psychodynamic and existentialist concepts have gained momentum there (J. Lopez-Ibor, R. Sarro), and psychiatry has been given more recognition, as evidenced by the Fourth World Congress of Psychiatry held in Madrid in 1966. Important studies on the history of psychiatry have been published there. *Portugal* has become known in psychiatry because of the introduction of frontal lobotomy there in 1936 by E. Moniz, who eventually received the Nobel Prize.

Among the various countries of the British Commonwealth, *Canada* has traditionally been in the unique position of economic and cultural dependence on the United States. In fact, developments in Canadian psychiatry have been often considered in conjunction with American psychiatry, and the interchange of professionals has always been very high (for example, C. Farrar from Toronto was for many years editor of the

American Journal of Psychiatry, and E. Cameron was elected president of the American Psychiatric Association). The psychoanalytic movement, first introduced by E. Jones in Toronto early in the century and then dependent on the British association, gained autonomous status in the fifties. It has been heavily influenced by Catholic philosophy in the French province of Quebec (for example, by K. Stern in his *The Third Revolution* and by N. Mailloux at his Centre d'Orientation for delinquent adolescents in Montreal), where religious orders have taken care of institutionalized mental patients for the past two centuries. Academic psychiatry has been particularly cultivated in Toronto (mainly at the Toronto General Hospital and at Clarke Institute founded in 1966) and in Montreal, where the Allen Memorial Institute at McGill University (opened by E. Cameron in 1944) has acquired prominence through the work by E. Wittkower on psychosomatic medicine and transcultural psychiatry, R. Cleghorn on neuroendocrinology, H. Lehmann on psychopharmacology, as well as through the participation of fine neurologists (W. Penfield, H. Jasper, F. Gibbs, E. Gibbs, and H. Selye, who described the general adaptation syndrome). Since the 1,600 practicing psychiatrists are mainly located on the east and west coasts, efforts have been made (for example, through the report *More for the Mind* published in 1963 by the Canadian Mental Health Association under the leadership of J. Griffin) to establish a network of services of community psychiatry throughout the whole nation. Such an endeavor, also supported by the Canadian Psychiatric

Association (founded in 1951), has already led to considerable progress in some provinces, notably in Saskatchewan, as reported in the *Canadian Psychiatric Association Journal* published since 1956. The Third World Congress of Psychiatry was held in Montreal in 1961.

In *Australia* the 500 practicing psychiatrists are increasingly involved in a vast program of mental health services (following the project initially developed by the State of Victoria, where a Mental Health Research Institute has been operating under A. Stoller since 1955), while relatively few take part in the psychoanalytic movement (at the Melbourne Institute of Psychotherapy).

In *South Africa, Hong Kong,* and other countries of the Commonwealth, aside from development of the Western practice of psychiatry, important research on transcultural psychiatry has been carried on.

Israel, a small and young nation, offers a great deal of interest for psychiatry. Even before that country officially became independent in 1948, some psychoanalysts practiced there: M. Eitington from Berlin, P. Wolff from Russia, and E. Neumann of the Jungian school. Since its founding Israel has become a fertile ground for psychiatry in three main areas: (1) coping with psychiatric problems of migration and acculturation, related to the rapid conglomeration of people from many parts of the world (for example,

Migration and Belonging by A. Weinberg); (2) establishment of a decentralized program of community psychiatry (in general hospitals, special centers, "therapeutic communities," and "work villages") facilitated by the lack of a tradition of institutional psychiatry; (3) relevance for personality development and psychopathology of raising children in the collective form of the kibbutz, made the subject of many studies even by American authors. In the academic field psychiatry is cultivated at Tel Aviv University and Hadassah University in Jerusalem, and research is published in the *Israel Annals of Psychiatry and Related Disciplines.*

Psychiatry in *Latin America* offers a very complex and varied impression owing to marked differences in the ethnic composition (especially Indians), geographical and cultural situation, economic and social level in each country, in addition to the unstable political scene. Yet certain common trends can definitely be seen everywhere: Western psychiatry has tended to be practiced mainly in urban areas under the strict leadership of a university professor; the prevailing psychiatric orientation was dependent on the French tradition in the mid-nineteenth century, later on the German tradition, and after World War II on the American tradition; in many countries methods of indigenous psychological healing continued to be practiced in preliterate cultures, though increasingly influenced by Western civilization.

The efforts made toward improvement in the field of psychiatry by the

Inter-American Council of Psychiatric Associations—including the American, the Canadian, and the Latin American Associations—have led to rather meager results thus far. In general, most of the broad long-range projects initiated in Latin America tend to achieve limited results because of social and political difficulties.

Puerto Rico is in a particular situation, since a considerable percentage of its population has relocated itself in the United States since the end of World War II. From the psychiatric perspective two main areas are thus identifiable: (1) the psychiatric problems presented by those who decided to resettle in American communities, related to the dynamics of separation from their background and difficulties in acculturation (language barriers, loss of the extended family, stress of urbanization and industrialization, and so forth) and resulting in a colorful psychopathology characterized by the so-called Puerto Rican syndrome " (a sort of hysteric attack highlighted by sudden loss of control, falling to the floor, and hyperkinetic movements of various kinds), frequent suicide attempts, and a high percentage of psychosomatic (especially asthmatic) disorders, for which short-term psychotherapy and chemotherapy carried on in emergency services and storefront facilities appear most successful; (2) the psychiatric problems of the population remaining in Puerto Rico, taken care of by about 100 psychiatrists. Most work in institutional settings, and others are connected with the Puerto Rican Institute of Psychiatry, reorganized in 1958 with American help but

functioning under local leadership (E. Maldonado, R. Fernandez, and others).

In *Mexico* the American influence has been particularly strong, both in the overall field of psychiatry (mainly represented by A. Millan, R. de LaFuente, J. Velasco Alzaga, and others) and in psychoanalysis (E. Fromm has been active since 1951), as evidenced by the Fifth World Congress of Psychiatry held in Mexico City at the end of 1971. Knowledge of the family and cultural background underlying individual psychopathology (extended family, masculinity of the man and dependence of the woman, formalistic expressions of social behavior, etc.) has been increased through the anthropological books of O. Lewis *(Life in a Mexican Village,* 1951).

In *Cuba* the traditional American influence on psychiatry has been drastically reduced by the advent of the Marxist regime. A magazine on transcultural psychiatry *Revista de Psiquiatria Transcultural* is edited there by the leading psychiatrist, J. Bustamante. Likewise, it is difficult to assess the position of psychiatry in *Chile,* where psychodynamic concepts were introduced in the past (mainly by J. Matte-Blanco and C. Nassar), after the rise to power of the leftist government of the physician S. Allende, who was himself interested in mental health in the thirties.

In contrast, the situation has remained more conservative in *Colombia,* where C. Leon is the most active psychiatrist, and in *Peru,* where

psychodynamic notions were introduced first by H. Delgado and later by C. Seguin and where an Institute of Social Psychiatry was founded in 1967 at the University of San Marcos in Lima, the oldest medical school in the American continent.

In *Brazil* psychiatry has developed mainly in the coastal cities, while in the interior—as in other Latin American countries—systems of healing are still carried on in the traditional framework of preliterate societies. In Rio de Janeiro after World War II the German-born W. Kemper introduced psychoanalysis and the Spanish-born E. Mira was active in various areas of psychiatry. More recently impetus for psychiatry has been provided in Sao Paulo by A. Pacheco e Silva.

Finally in *Argentina* psychiatry and, in particular, psychoanalysis have acquired a great deal of acceptance, probably as a result of the immigration there of some Jews from Central Europe in the thirties, followed by many other immigrants in the late forties. All this overshadowed the fact that important pioneering work in psychiatry by some pupils of the Italian Lombroso had taken place there early in the century. The Argentine Psychoanalytic Association, founded in 1942, publishes the important *Revista de Psicoanalisis* of eclectic orientation (that is, influenced by Kleinian, Adlerian, and Jungian trends). Recently some have followed Pavlovian concepts. Among the professionals recognition has been won by A. Garma for

his studies on peptic ulcer and by E. Krapf for his influence in the academic field. A National Institute of Mental Health, aimed at providing better facilities for the mentally ill throughout the whole country, was founded in 1957.

Russia and the communist countries offer a rather complex and varied picture from the historical perspective. Russia and Yugoslavia present a manifold background in terms of ethnic, linguistic, and religious dimensions; in most communist countries, with the exception of Czechoslovakia and, to a less extent, of Russia, an agricultural economy prevails. Also their allegiance to the Marxist doctrine is not homogeneous. In terms of psychiatry proper, Western influences have always been prominent, first the German organicistic school in the mid-nineteenth century, then the French clinical school of hypnosis at the end of the century, followed by a short-term Freudian orientation in the twenties, and, from then on, by the Pavlovian doctrine. "

Russian psychiatry remained virtually unknown to the United States because of the reciprocal attitude of diffidence and lack of contact. Since foreign travelers have been admitted to communist countries in the last decade, a number of reports (including an official one by a special mission of the American Psychiatric Association in 1967) have become available. It has been found that Russia has developed a network of services for mental patients, first at the level of the polyclinic (one for every 5,000 people), then

the neuropsychiatric dispensary (one for every 500,000 people), and finally the district mental hospital, in all of which extensive work on prophylaxis, diagnosis, and rehabilitation takes place. Such work is possible because of the large number of physicians (more than 600,000 mostly women), nurses, and medical technicians (that is, paraprofessionals, called "feldshers") available in community facilities as well as in mental hospitals (where the ratio of physicians to patients is 1:16). Therapy centers around social readaptation, by keeping patients as "vertical" as possible and by the eclectic use of short-term supportive relationship, chemotherapy, suggestion (up to hypnosis), and an extensive program of day care (initiated in 1930) and sheltered workshops, often in conjunction with industries. In contrast to the United States, the conception of psychiatry from the narrow "medical" perspective (reinforced by the view of psychodynamics as linked to the bourgeois system), " with the consequent complete absence of the collateral fields of clinical psychology and social work, the limited research facilities (mainly at two centers in Moscow and Leningrad), and the recently established complacency of some psychiatric hospitals in certifying as mentally ill enemies of the regime have naturally been seen in a very negative light.

Despite this, Soviet psychiatry, in the past considered backward from the psychoanalytic viewpoint, has recently elicited a favorable or at least an interested attitude in this country for two reasons: from the perspective of therapy, because of the spread of behavior therapy, whose philosophy has

been heavily influenced by Pavlovian notions; from the perspective of community psychiatry, because of the apparent success achieved in providing services for the mentally disturbed at the community and district level. Aside from the 20-year-old monograph on Soviet psychiatry by J. Wortis, the recent historical study by J. Brozek and D. Slobin, and some reports by Russian authors translated into English, much more direct knowledge of psychiatry, especially in relation both to the scientific attitude and the political dimension, is needed. It looks as if both the United States and Russia may gain from the reciprocal observation of their psychiatric systems.

The other *communist countries* present considerable differences from Russia because of the reasons mentioned above, in spite of the efforts made by them to introduce a national system of psychiatric services early in the fifties. *East Germany, Hungary, Czechoslovakia,* and the *Croatian part of Yugoslavia* tend to be heavily influenced by Western psychiatric concepts, which had a long tradition in each one of them. In *Poland* much of the care for the institutionalized mentally ill is still in the hands of Catholic orders, while in *Bulgaria* and *Runumia,* as in the rest of the communist countries, systems based on Pavlovian principles are reinforced under the pressure of political forces. Even more than for Russia, firsthand reports (with the exception of the books edited by A. Kiev and by J. Masserman, respectively) are lacking.

Psychiatry in the Countries of the Far Eastern Tradition

From an overall historical perspective—and taking into consideration the need to simplify matters in a short historical presentation—the countries of the Far Eastern tradition can roughly be divided into three types: (1) those that developed as part of the British Commonwealth (India, Ceylon, etc); (2) those in which psychiatry consisted of the amalgamation of autochthonous practices and Western concepts (Japan, Philippines, Taiwan); (3) and those in which indigenous practices were only very limitedly influenced by foreign notions.

In *India* official psychiatry was once represented by the Indian Division of Royal Medico-Psychological Association, which in 1947 became the Indian Psychiatric Society. Today there are about 200 psychiatrists for a population of more than 500 million. Psychiatric facilities tend to be undeveloped, and many mentally ill receive minimal care in their communities. Worth mentioning is the rapprochement between traditional Hindu concepts of the mind (yoga and others) and some contemporary Western systems.

In *Japan* academic psychiatry was in the past heavily influenced by the German school, while, in general, the attitude toward the mentally ill was rather punitive or neglectful (with some exceptions, such as the system of community care practiced at Iwakura, near Kyoto). In the late twenties the psychoanalytic movement had a number of followers there, especially in the large cities, although in retrospect it appears that Freudian notions were

basically modified by local customs— childrearing, role of the woman, servile attitude toward the elders and, in particular, the Emperor, and, in general, ambivalence toward Western progress, admired but also hated (J. Moloney's *Understanding the Japanese Mind,* 1954). Around the same time the so-called Morita therapy (named after the Tokyo psychiatrist S. Morita) was introduced, with a moderate degree of success that has persisted to the present. Essentially intended for patients suffering from neuroses and compulsions (common in Japan because of the tendency of people to internalize conflicts), this method consists of a period of complete isolation in bed, followed by progressive activity up to reinsertion in the community, carried on in a rigidly established situation of complete dependency by the patient on the doctor and the nurse (which has prompted the psychoanalytic view of Morita therapy as regression followed by "corrective ego experience"). As a result of the American involvement with Japan during World War II, firsthand anthropological studies were made on the whole Japanese culture by R. Benedict (*The Chrysanthemum and the Sword,* 1946), followed more recently by social psychological studies on attitudes and practices toward the mentally ill (mainly by W. Caudill, T. Doi, C. Schooler, and others). Since then Japanese psychiatry has been greatly influenced by American trends, also through joint meetings (such as the one between the American and Japanese Psychiatric Associations in 1963). Today many of the 4,000 psychiatrists tend to follow eclectically the organicistie and

psychodynamic schools. Regardless of differences in orientation, the importance of cultural factors stands out: close, almost symbiotic, relationship between mother and child; intense repression of feelings; conflicts between individuality and collaterality of family members; and especially conflicts between allegiance to traditional values and identification with Western mores.

In *China,* a gigantic country relatively little influenced by Western civilization, attitudes toward the mentally ill depend heavily on autochthonous cultural beliefs. Proper behavior is related to Tao, mainly based on reverence to the ancestors and on the public image of each individual; disregard for Tao may cause an imbalance between the two basic forces Yin and Yang, to which are subjected the various organs and channels connecting the inside to the periphery and the five constituents of the body, that is, earth, fire, water, wood, and metal. Since early times (such as in *The Yellow Emperor's Classic of Internal Medicine,* about 1,000 b.c.) the treatment of mental illness consisted of acupuncture and moxibustion (application of needles and of ignited substances at the surface of the body) to facilitate the flow of Yin and Yang along the proper channels. In the coastal cities of Canton, Shanghai, and a few others, Western practices were introduced a century ago mainly by American missionaries, so that the few psychiatrists came to be influenced by Meyer's psychobiology. Dr. K. Bowman, sent there in 1947 by the United Nations to help organize the National Neuropsychiatric Institute,

reported that there were about 50 psychiatrists and 6,000 psychiatric beds. Since the communists took over in 1949, psychiatry has come to be seen from the Pavlovian perspective, although Mao Tse-Tung's writings are important in terms of prevention, as they stress priority of services to the masses, combination of mental hygiene and public health, and amalgamation of local and Western systems. Eventually the Chinese Society of Neurology and Psychiatry and the *Chinese Neurological and Psychiatric Journal* came into existence, psychiatric training was introduced in all 50 medical schools, and to the regularly trained physicians were added many paraprofessionals ("barefoot doctors" or "peasant-scientists"), especially in the rural areas. Regardless of the theoretical emphasis (strictly Pavlovian in the fifties when politically China was very close to Russia, more a combination of indigenous and Western practices from the mid-sixties on), milieu therapy focused on group sessions directed toward ideological discussions has received the primary emphasis, in addition to physical treatment and chemotherapy. This may be justified from a perspective that considers mental disorders essentially as social problems, but it leaves unanswered some basic questions related to the individual's inability to express feelings openly, even in his own family, and to the emotional transferal of areas of personal life to a society that is based on austerity and purposefulness of common ideals. These various points have many implications for mental health from the Western psychodynamic perspective and need further assessment.

Psychiatry at the International Level

As mentioned above, cross-cultural and transcultural psychiatry will be presented in detail in other parts of this work. Here it is enough to mention the change in the methodological approach to the study of non-Western culture that has taken place during the period considered in this chapter, from the traditional psychoanalytic model of "culture and personality" (for example, E. Sapir, R. Benedict, M. Mead, C. DuBois, M. Opler, A. Kardiner, A. Kluckhohn and, among the opponents of psychoanalysis, B. Malinowski and A. Krober) to a broader multidimensional perspective by interdisciplinary teams. As an example of this switch, the volume by Carothers on the African mind (1953), which he considered incapable of reaching the level of Western sophistication, is today already obsolete. Impetus toward research on mental disorders in other countries has come from the rapidly increasing contacts among people of different nations since the end of World War II and, even more, from the rise of many independent nations in the Afro-Asian areas.

In connection with this latter event governments all over the world are involved in making plans for prevention, treatment, and rehabilitation of the mentally ill, often relying on a combination of Western and local practices. The role of the United States has been so prominent in helping these various governments in this endeavor as to justify the separate presentation of this matter in the present section.

However, some essential preliminary points have to be mentioned on the basis of recent studies (such as the comprehensive survey by A. Kiev): the scientific approach attempts to explain *how,* folk attitudes *why* (e.g., influence of evil spirits) mental disorders occur; the incidence of severe psychopathology is constant everywhere, but the content (e.g., hallucinations or delusions) and the form (e.g., unusual syndromes due to altered states of consciousness) are different in each culture, according to its meaning (compensatory or pathoplastic) and methods of healing (e.g., cathartic); depending on the social expectation of the role played by the mentally ill (G. Devereux), in each culture certain diagnoses are emphasized or not (e.g., alcoholism, homosexuality) and occur more often than others (e.g., frequent acute schizophrenic breakdown versus rare depressive conditions in Africa); in each culture are to be found healers of mental disorders, whose methods are based on a mixture of exorcism, drugs, and particular rituals, such as the interpretation of dreams; rapid social changes occurring mainly in Afro-Asian countries tend to result in stress that facilitates the rise of messianic and superstitious cults.

Taking these various points into consideration, it becomes understandable why it is difficult to establish common criteria to obtain epidemiological data on mental disorders in underdeveloped countries, where hospital facilities are rare, life expectancy is shorter, and migrations as well as political and social conflicts (urbanization, industrialization, etc.) are

frequent. It also becomes understandable why in many countries the tendency has prevailed to combine local and Western practices in the handling of psychiatric disorders with the help of nurses and paraprofessionals and the support of indigenous leaders and groups, resulting in efficient types of care, for instance, at the Aro Mental Hospital in Abeokuta, Nigeria (opened in 1954 and described by T. Lambo and others), where a high percentage of patients live in villages under the supervision of trained personnel.

Three institutions have been particularly active in the organizational field of mental health: the World Federation for Mental Health, the World Health Organization, and the World Psychiatric Association.

Founded in 1948 in London (in connection with the Third International Congress in Mental Health), the World Federation for Mental Health, under the dedicated leadership of few professionals (first the British J. Rees, then the Swiss A. Repond, the Americans F. Freemont-Smith, O. Klineberg, G. Stevenson, J. Millet, and others), has been instrumental in providing publications, seminars, workshops, lectures, and research on various aspects of mental hygiene.

Likewise, meetings on many topics related to psychiatry have been sponsored by the World Health Organization (established as an agency of the

United Nations in Geneva in 1949 and composed of five regional offices, one for each continent) with the support of an expert advisory panel and various study groups. In addition, the WHO has published important monographs on juvenile delinquency (by L. Bovet, 1951) on maternal care and mental health (by J. Bowlby, 1952), and on other subjects.

The World Psychiatric Association was founded in 1961, at the time of the Third World Congress of Psychiatry held in Montreal; the late E. Cameron was elected the first president. Through the dedication of many psychiatrists (mainly the French J. Delay, H. Ey, and P. Sivadon, the Spanish J. Lopez-Ibor, the Swiss M. Bleuler, the British D. Leigh and J. Wing, and the American H. Tompkins, D. Blain, and F. Braceland), it has fostered the dissemination of professional information among 72 national psychiatric organizations, representing more than 63,000 practitioners throughout the world (as evidenced by the new *Directory of World Psychiatry,* edited by J. Gunn), and has organized technical sections, symposia, and regional meetings on various subjects.

Among the other worldwide organizations are the European Association of Child Psychiatrists, the International Society for Social Psychiatry, the International Association of Child Psychiatry, and the recently established Association of Psychiatrists in Africa (actually Pan-African Psychiatric Conferences have been held there since 1961). The *International Journal of*

Psychiatry has been edited by J. Aronson in New York City since 1963, while, among the developing nations, the periodical *Pstjchopathologie Africaine* has appeared in Dakar since 1965.

Epilogue

In 1959, at the conclusion of the first edition of this chapter, the question of the responsibility of American psychiatry toward the mental health goals of the future was raised. That same year Karl Menninger, a senior psychiatrist, in his Academic Lecture entitled "Hope," reminded his audience of the words pronounced by Ernest Southard , a pioneer in broadening the scope of psychiatry, in 1919:

> "May we not rejoice that we [psychiatrists] . . . are to be equipped by training and experience better, perhaps, than any other men to see through the apparent terrors of anarchism, of violence, of destructiveness, or paranoia— whether these tendencies are showing in capitalists or in labor leaders, in universities or in tenements, in Congress or under deserted culverts. . . . Psychiatrists must carry their analytic powers, their ingrained optimism and their strength of purpose not merely into the narrow circle of frank disease, but, like Seguin of old, into education; like William James, into the sphere of morals; like Isaac Ray, into jurisprudence; and, above all, into economics and industry. I salute the coming years as high years for psychiatrists!"

It took half a century before American psychiatry woke up to its responsibility toward all the citizens of the nations. For the historian it is important to determine the main currents that have created this situation, beginning with the discussion on transcultural, cross-cultural, and international psychiatry in the previous section.

There it was established that American psychiatry had played an

increasingly important role at the international level, first through research on transcultural and cross-cultural dimensions, followed by forms of assistance to European countries affected by World War II and, later on, to newly emerging Afro-Asian countries. Actually interest in international matters on the part of this country can be traced back to the establishment of the International Committee on Mental Hygiene in 1918 (preceded by the National Association for Mental Health, 1909), which organized the First International Congress for Mental Health in Washington, D.C., in 1930, and to involvement on the part of the American Psychiatric Association (through joint meetings with other national associations and the work of various committees), aside from the substantial support given to the United Nations.

Direct psychiatric influence at the international level can also be related to the pre-World War II practice of obtaining training in European facilities (mainly England) by a few American psychiatrists, and vice versa. Following the end of the war, with the help of various organizations, a good number of European physicians received training in this country in the fifties; in fact, some of them eventually settled permanently in this country. In the sixties the majority of the foreign physicians in training came from developing Far Eastern nations (India, Korea, Philippines); in fact, during the academic year 1967-1968 more than 30 percent of the psychiatric trainees were graduates of foreign medical schools. This puts this country in a position of ambiguous responsibility: on the one hand, it allows foreign graduates to provide

necessary manpower to poorly staffed public facilities; on the other hand, America has a commitment to developing countries to help train staff for their own programs.

The issue of the responsibility of American psychiatry at the international level increasingly has become related to the developments that have taken place in this country. Through a convergence of important studies (mainly J. Galbraith's *The Affluent Society,* 1958, and M. Harrington's *The Other America,* 1963), widely publicized campaigns (bus boycotts, ghetto riots, and the Poor People's March), and some important judicial and political actions (the 1954 Supreme Court decisions to outlaw segregation in public education, President Johnson's War on Poverty, etc.), this country has become aware, as never before, of large areas of poverty and deep racial and social conflicts. As a result of this new awareness, the community mental health movement, discussed in detail in another section of this chapter, has been taking place.

Such a movement, however, cannot be properly implemented only through legislation or allocation of funds, but requires the active participation of many people at various levels eager to modify the traditionally middle-class oriented psychiatric philosophy to be of more relevance to large segments of low-income population. Some modest attempts have already been made, such as introducing proper therapeutic modalities (E. Auerswald,

S. Minuchin, F. Riessman, and others), assessing community-based facilities in some areas (for example, in a section of New York City by L. Kolb and associates in *Urban Challenge to Psychiatry,* 1969), and encouraging well-motivated people to become paraprofessionals (or "indigenous workers or mental health expediters").

In view of all this, the situation of psychiatry in many other parts of the world, where poverty and social conflicts are endemic, has become quite relevant to this country. While, from the psychoanalytic perspective of the fifties, psychiatry in practically all the rest of the world was seen as inferior to American standards, from the perspective of the community mental health movement of the sixties, systems of care and treatment of the mentally ill used in underdeveloped countries as well as countries of the communist bloc may very well acquire a great deal of importance for American psychiatry. This ranges from a more tolerant attitude toward the mentally disturbed by the general population, to the development of community-based facilities, to the extensive use of paraprofessionals of all types. Therefore, the mission grandiosely held by American psychiatry on the wave of the military victory of World War II, of disseminating everywhere psychodynamic principles leading to intensive therapeutic relationships, has been replaced by a more modest philosophy of individual treatment and, by a thorough commitment toward prevention and help to many more people throughout the country. Moreover, Western psychodynamic principles, seen from the broad cross-

cultural perspective, have been found to share many similarities with indigenous forms of treatment based on public expression of feelings practiced in many countries by recognized healers; and, likewise, research in the context of other cultures (for example, on the phenomenology of the person in the Yoruba society by I. Laleye and on the African Oedipus by M. Ortigues and E. Ortigues) has pointed to the relativity of some dynamic notions traditionally held to be universal. Finally from the historical perspective the tendency toward internationalization of many issues (from youth revolt to drug abuse) and toward worldwide cooperation (e.g., in space exploration and in ecological projects) cannot but affect also the field of psychiatry.

In reference to history, the thesis recently presented in the volume *A Social History of Helping Services (*1970) by M. Levine and A. Levine that periods of prevailing "intrapsychic models of help" (that is, psychodynamic) in eras of political conservatism alternate to periods of prevailing "situational modes of help" (that is, community mental health) in eras of social reforms, may be debatable. The fact remains, however, that historically a definite change is taking place in the role of psychiatry from the viewpoint of the psychiatric profession itself, of the patient, and of the public at large.

In regard to the psychiatric profession, the aristocratic image presented by psychiatrists in the past (R. Holt's *Personality Patterns of Psychiatrists,*

1958) is being challenged by the notion that there are few differences between psychoanalysts, psychiatrists, psychologists, and social workers (W. Henry, *et al., The Fifth Profession,* 1971), especially if psychotherapy is seen as "the purchase of a friendship" (W. Schofield). Most psychiatrists tend to be influenced by the organicistic, the individual, or the community model (E. Strauss, 1964), quite often in a rather narrow way (W. Freeman, 1968). In reality the first two models are the most pervasive, while thus far community action has not attracted many, as shown in the thorough study by A. Rogow. Claims of psychoanalytic contributions to community action (in D. Milman and G. Goldman's *The Psychoanalytic Contributions to Community Psychiatry,* 1971) or of substantial progress achieved through preventive programs (in *Crisis in Child Mental Health Challenge for the 1970s,* 1970, which is the report of the Joint Commission of Mental Health of Children) are far from being substantiated.

Very little has been said by patients in regard to their treatment. F. Redlich has been among the few who has attempted to answer the question of how a person finds a psychiatrist (*Harper's,* 1960). The results of his own research (with Hollingshead, 1959), that low-income people tend to receive organic treatment in institutions and middle-class people psychotherapy in outpatient clinics, have not been substantially modified by the follow-up study by J. Myers and L. Beam (1968). There is a need for studies along the lines of H. Strupp's *Patients View Their Psychotherapy* (1969).

From the broad perspective of the public several studies are available, all pointing to the fact that the majority of people tend to turn for help to other kinds of healers (mainly clergymen) before going to psychiatrists (M. Krout's *Psychology, Psychiatry and the Public Interest,* 1956; J. Nunnally's *Popular Conceptions of Mental Health,* 1961; Elison's *Public Image of Mental Health Services,* 1967; C. Kadushin's *Why People Go to Psychiatrists,* 1969).

It is questionable whether the above trend depends on the shortage of psychiatrists or rather on the widespread ambiguity toward psychiatry. The shortage of psychiatric manpower is still grave, although psychiatry has become the third most frequent choice of specialty by young physicians after medicine and surgery, and there has been massive federal support of training programs and ingenious attempts to encourage students to enter this field (for example, with the booklet *Careers in Psychiatry,* published by the National Commission on Mental Health Manpower, 1968). Efforts to train paraprofessionals are certainly very laudable, although in reality their effectiveness is handicapped by the conflict between their identification with the values of the professionals and their allegiance to their own values.

The issue of values needs to be mentioned at this point. In the past psychiatry, as a field of medicine, has been seen from the traditional perspective of medical ethics. The early psychoanalytic movement, stemming from a highly homogeneous patriarchal society, beginning with Freud

assumed that values were not relevant to psychiatry. This notion was later challenged by many who became aware of the unconscious identification of the patient with the therapist's own values. In the fifties, during the short period of the rise of existentialism, values in psychiatry constituted the subject of considerable discussion (for example, C. Buhler's *Values in Psychotherapy,* 1962).

In the last decade the main issue in regard to values has shifted from medical ethics to a much broader perspective involving the responsibility of the psychiatrist as a professional and as a citizen. This shift has been influenced by several events: in the mental health field, the controversies generated by the many publications of T. Szasz indicating that psychiatrists perpetuate the "myth of mental illness" by supporting attitudes that place certain individuals in the role of the mentally ill; in the academic field, the bipolarity between Skinner's behavioristic model of personality and Allport's and Maslow's humanistic psychology; on a larger scale, the ambiguous image offered by psychiatry in relation to matters such as professional assessment of political figures (especially at the time of the 1964 Presidential election), the Vietnam War, the youth unrest, the spread of drug addiction, the fight against poverty, the ethnic conflicts, and the epidemics of violence.

The fact that many of these latter problems transcend the boundaries of our nation should not deter American psychiatrists from meaningful

involvement, taking into consideration, of course, the possibility of conflict between confidentiality to the patient and service to the community. This is the position officially taken by the Group for the Advancement of Psychiatry in *Psychiatry and Public Affairs,* 1966.

Deep-seated attitudes are difficult to modify, even in psychiatrists, as recently shown, for instance, in J. Kovel's *White Racism: A Psychohistory* (1970) and in T. Thomas and J. Sillen's *Racism and Psychiatry* (1972). There is evidence, however, that a new breed of young psychiatrists is emerging, committed to alleviating people's miseries at every level quite at variance with the traditional cliche of the psychoanalyst exclusively involved with a sophisticated clientele. The publications by R. Coles on underprivileged children, by M. Dumont *(The Absurd Healer,* 1969), by R. Leifer *(In the Name of Mental Health,* 1969), and by others on the uncertain role of the psychiatrist at present are expressions of this trend. Also notable are the liberal attitude of some psychiatrists toward the use of drugs and toward sexual behavior (especially homosexuality), as evidenced by the research of R. Masters and V. Johnson at the Reproductive Biology Research Foundation in St. Louis. The American Psychiatric Association has sponsored studies on violence and current president, A. Freedman, has been elected with the support of the Committee for Concerned Psychiatrists, a newly formed group directed toward social action.

All this points to the fact that in a matter of a few years a generation gap appears to have developed between the traditionally oriented psychiatrists, who still control many academic positions, and many socially committed psychiatrists. Certainly, on the one hand, the latter should realize that psychiatry (called "the uncertain science" in a thorough survey in a popular magazine, 1968) cannot be the answer to all problems, especially after J. Seeley has convincingly showed that increasingly psychiatry is expected to take over the roles left by the decline of traditional social and religious institutions. On the other hand, inactivity vis-a-vis urgent issues is in itself a decision, as cogently pointed out by S. Halleck in *The Politics of Therapy* (1971).

As stressed in an exceedingly stimulating paper by the distinguished historian, Stuart Hugues, at the 1969 convention of the American Psychiatric Association, society, rather than the patient, appears to be sick today. Yet the irrational expressions of many, up to despair, should not deter us from reason: "Sooner or later," he concluded, "the soft voice of reason will be heard once again."

These words appear to echo the prophetic statement made in 1944 by Alan Gregg, a great mentor of our profession, on the occasion of the centenary of the American Psychiatric Association:

"Psychiatry, along with the other natural sciences, leads to a life of reason. .

. . Psychiatry gives us a sort of oneness-with- others, a kind of exquisite communion with all humanity, past, present and future. . . . Psychiatry makes possible a kind of sincere humanity and naturalness. . . . Psychiatry makes it possible *to bring to others* these things I have mentioned. . . . Also it makes one able to receive these same gifts."

Perhaps looking back at history may represent for American psychiatry a source of confidence in meeting the great challenge of the future. This interest in history may be essential for the rise of a new humanism to which psychiatry, imbued with science and humanity, can validly contribute.

Bibliography

In view of the historical and general character of this chapter, the following principles have been followed in the preparation of the bibliography:

1. Well-known books are cited in the text only, together with the name of their authors. They are not listed in the bibliography because the complete reference is given in other chapters dealing specifically with the topic to which the book refers.

2. Full reference is given in the bibliography to the books and articles that belong to the following categories:

   a. Historical material, especially if concerned with broad issues.

   b. Surveys of a particular topic that of fer a view of its development.

c. Specific articles that historically represent the beginning of a new field.

d. Contributions by American authors.

As bibliographical guides to the psychiatric literature, the two following comprehensive books are available:

Ennis, B., *Guide to the Literature in Psychiatry,* Partridge, Los Angeles, 1971. Menninger, K., A *Guide to Psychiatric Books in English,* 3rd ed., Grune & Stratton, New York, 1972.

Abroms, G. M., "A New Eclecticism," *Arch. Gen. Psychiat.*, 20.514-523, 1969.

Chapter 4

A General Assessment of Psychiatry

Alfred H. Rifkin

To assess is to determine the amount or worth of, to appraise, to evaluate, to take the measure of. We do not ordinarily consider assessing fields like cardiology, ophthalmology, or pediatrics in the sense of determining their worth, although we may inquire into the efficacy of a particular procedure or a medication. Yet it seems appropriate to seek a general assessment of psychiatry. Why? The question reflects a certain uneasiness, a need to clarify the scope of psychiatry, to fix the proper limits of its concern, to determine the nature of the problems to which it should address itself, and to study the conceptual and technical tools fashioned for the solution of problems. What is to be measured and evaluated? Shall it be the diagnostic scheme and the

criteria for health or illness, the "cure" rate achieved by different treatments, the incidence and prevalence of specified disorders, or the various theories and schools of thought? These questions do not have merely academic or theoretical interest; they are of direct and immediate concern in determining many matters of public policy; in assigning investigative priorities; in allocating resources, funds, and personnel; and in establishing programs of education and training for the mental health professions.

A proper assessment of psychiatry requires that the subject be viewed in historical perspective. The physical sciences, dealing with relatively discrete phenomena amenable to direct observation or experimentation, and aided by the powerful tools of mathematics, were the first to emerge from speculative philosophy. Medicine as a whole was slower to emerge, but its scientific foundations were laid in the sixteenth and seventeenth centuries by anatomical investigations, the discovery of basic physiological functions, and

the gradual delineation of clinical pictures. Psychiatry lagged behind as the understanding of human behavior long remained the province of metaphysics and theology. In general, "schools" of medicine faded as cellular pathology and bacteriology established a firm basis for understanding disease processes and their treatment. Today there are hardly any remnants of the great controversies that raged around bloodletting and purgation, or homeopathy versus allopathy. But it was not until 1824- 1825 that J. F. Herbart, a philosopher and educator, published his *Psychology as Science, Newly Based on Experience, Metaphysics, and Mathematics.'*The steps forward as well as the burdens of the past are evident in this title. It was several decades later before Gustav Fechner demonstrated that psychological functions are amenable to experimental measurement, and only in 1879 did Wilhelm Wundt establish the first psychological laboratory. Mechanism and vitalism are no longer urgent issues, but psychogenesis, the modern descendant of the ancient body-mind dilemma, remains a subject of lively contention in

psychiatry. Deeply rooted schisms abound that are not differences in emphasis or variations in technique but fundamental divergences in conceptualization.

Practical limitations require that an assessment of psychiatry must be selective rather than exhaustive. Ideally it should deal with trends and lines of development insofar as these can be discerned, rather than with specific syndromes or procedures. The most significant and most difficult task is to identify central themes and problems, and the strategies devised to explore them.

Schools of Thought

The first matter that calls for attention and appraisal is the prominence of schools of thought. There are many lines of cleavage that take on the qualities of slogans: organic versus psychogenic, heredity and constitution versus life experiences, instinct versus culture, psychotherapy versus

chemotherapy or psychosurgery, depth analysis versus "behavioristic" symptom elimination, the medical model versus game theory and social learning. Such profound differences in approach have few, if any, parallels in other branches of medicine. It is often said that theories flourish where ascertainable facts are few. In principle a theory is not provable in any absolute sense; it merely becomes more plausible and perhaps more useful as observations consistent with it accumulate. Furthermore, a theory must be of such form and content that it may be refuted by some crucial observation. The problem for psychiatry is that these conditions are difficult to fulfill. On the contrary, observations may often be marshaled in support of several competing theories, while none is conclusively refuted. These strictures apply to most psychiatric theorizing, but are most often raised against psychodynamic, especially psychoanalytic, theories. Shall we then accept Jaspers' view that ". . . in psychopathology there are no proper theories as in the natural sciences"?

Concerned as it is with disorders of human behavior, psychiatry must take into account a truly overwhelming diversity of factors and variables. To deal with the vast array, to apply the available modes of reasoning and investigation, this complexity must be simplified and ordered. This is the basic function of schools of thought. Each school of thought offers a body of theory that provides a framework upon which to arrange the data of experience, observation, and experiment. Theory directs attention to certain phenomena in preference to others, determines what will be considered important or relevant and what will be disregarded or dismissed. Theory is also limiting. Applying Sapir's viewpoint we may posit that each school of thought establishes its own language, which classifies, organizes, and to a significant degree predetermines experience for its users. Theory projects meaning into experience and imposes certain modes of observation and interpretation.

It is hardly possible to make a full inventory of the various theories of human behavior, but some useful categories may be delineated. Every individual is part of many interlocking and interacting systems or levels of integration. Within himself he is a delicately balanced set of chemical, physiological, and psychological subsystems. Each individual is also part of several systems of social interaction, extending from those with whom he is in closest contact to the widening circles comprised of groups of differing size, composition, and complexity to which he has some relationship. Psychiatry encompasses at one and the same time the scientific study of man on the biological level, the psychological study of the individual, and the sociological and anthropological study of human groups on a small and large scale. Not only is psychiatry concerned with these various levels of integration, but also it is a composite of all the levels. Collectively designated the behavioral sciences, these traditional disciplinary subdivisions reflect the course of historical development in the study of human behavior. They bring portions

of the subject matter within manageable bounds, but at the same time fragment our understanding.

Recognition of this fragmentation has had several significant consequences in psychiatry. In recent years there have been increasing efforts to make critical comparisons among different viewpoints as well as to develop "unified" theories. The rapid accumulation of information that characterizes the current era makes it less and less possible for any one individual to attain competence in several diverse fields, or even the subdivisions of any one discipline. As a result research efforts, journal articles, and books are more often group undertakings. On the other hand, professional training, institutional affiliation, and the scientific literature are still largely disciplinary.

The educational and organizational issues posed by this state of affairs will be discussed below in connection with some speculations about the

future of psychiatry. The more immediate need is to find ways to amalgamate information from the parochial fields of knowledge in usable fashion, given the present structure of the behavioral sciences. Several steps may be envisaged. The first and most obvious is exemplified by the multidisciplinary conferences and projects already mentioned. What can be expected of these? At the very least the results should include mutual enrichment of information, clarification of definitions and problems, and a deeper understanding of other viewpoints. The disciplines may be using different terminology for the same phenomena, but they may also be applying the same terminology to fundamentally different phenomena.

Beyond this it may be possible to identify related events at several levels of integration. Simple examples would take the form of parallelism or concomitance of chemical events and psychological states, or correlation between social class status and symptom patterns. Such studies usually fall

within the newly delineated fields of psychosomatic medicine and social psychiatry.

Psychosomatic medicine is confronted with "the mysterious leap from mind to body" and the reverse. Two major theoretical formulations have emerged: (1) certain bodily disorders are the consequence of physiological concomitants of psychological (mainly emotional) states; (2) certain bodily disorders are the symbolic expression of psychological states (mainly conflict or the need to communicate). Placing the "psycho" first seems to have meant for most users of the term that the psychological state is primary or causal. Recent findings and more detailed analysis indicate that the interrelationship is more complex. Thus Knapp formulates the issue as a series of feedback interactions that include social as well as psychological and physiological factors. Weiner, relying on other experimental data, sees concomitance that does not necessarily imply causality in either direction.

For social psychiatry the problem of interrelationships is likewise complex. Human survival requires that societal forms be consistent with basic biological needs. The well-documented variation encountered in different societies makes it clear that there is no simple translation of biological needs into cultural institutions. There are evidently many ways in which these needs can be met. The most direct formulations focus on ways in which society facilitates or hinders the expression or satisfaction of needs, with emphasis usually on the repressive aspects of the social system. These formulations are oversimplifications. Societies also create needs apparently as imperative as those ordinarily considered basic and biological. Furthermore, the impact of society on individual needs is not merely to hinder or facilitate. Bell, surveying the literature, lists some of the interrelationships postulated between individual and social variables: one step direct, one step indirect, two step direct, and two step indirect. Even this description is too schematic. Examination of various studies suggests there

are many interweaving processes and variables that operate to a greater or lesser degree simultaneously, such as frustration, disorganization, social change versus stability, definition versus ambiguity of role, and others. The problem in each instance is to specify the variables and the mode of interactions.

Many comprehensive formulations have been made. Knapp presents evidence for a "transactional model" in the etiology of bronchial asthma. Another sophisticated example is the investigation of genetic factors in schizophrenia originating in the National Institute of Mental Health. From a very carefully designed and executed series of studies summarized by Pollin, it appears that genetic factors are significant in this disorder and may consist of predispositions to abnormal metabolism of catecholamines and indolamines due to peculiarities in the inducibility of certain enzymes. Affected individuals therefore suffer a hypothesized hyperarousal state of the

nervous system that renders them specially vulnerable to stress. What is stressful, however, depends largely on the life history and experiences of the individual within his familial and sociocultural milieu.

Thus, we have pictured a sequence which involves an external event, the potential stressor— its resultant psychological meaning and signal, which is based on previous experience, role within the family and within the social structure—the resultant biochemical and physiologic response on the organ and cellular level, its extent determined in part by genetically controlled enzyme activity, and in part by changes in enzyme levels induced by previous experience.

In summary, experiential factors are seen as operating in four distinct ways. (1) They form the dictionary with which an individual translates the meaning and significance of any given current experience; and the yardstick by which he automatically measures the amount of threat, ie, stress, it constitutes for him. (2) Their residue determines the quantity and style of defenses and coping abilities with which the individual will attempt to deal with a stressful current life-situation. The determinants include such varied processes as the clarity of intrafamilial communication, the nature and extent of intrafamilial alliances and

identifications, and the pattern of perceptions and coping mechanisms associated with one's location in the social class matrix. (3) Prior experience determines, in part, the extent of biochemical response to stress by influencing the level of enzymes available, through enzyme induction. (4) It seems likely that certain events, possibly concentrated in the intrauterine period, are relevant because of a direct slight effect on CNS structure, ie, neonatal anoxia causing minimal brain changes that later appear as subtle decrease in the capacity to maintain focal attention. (Pollin, pp. 35-36)

This formulation is comprehensive and flexible enough to accommodate new findings at any level, including, for example, detailed investigations of formal thought disturbances, family constellations, or social class position. For the purposes of this general assessment it is not necessary to review the evidence for or against the various aspects of Pollin's thesis. Admittedly some portions are speculative. The significant advance is that investigations at different levels are not posed against one another as competing etiologies but are woven into a coherent whole. The concept of stress provides the

framework for relating the diverse disciplinary approaches. It also permits relatively simple organization and statistical analysis of data, mainly by treating stress as an intervening variable and relying on twins to equate genetic factors. Such simplifications are essential.

The underlying logic of most investigations depends on one or more of J. S. Mill's classical canons for discovery of causal relationships in which possibly relevant factors are made to vary one at a time. Twin studies are an elegant application of Mill's canons; the genetic factor is taken as constant so that the effects of other variables can be studied.

Even in the case of identical twins it is difficult fully to satisfy Mill's canons and keep factors truly constant. Differences of personality in identical twin pairs have been noted repeatedly along with many similarities. Pollin cites a twin pair only one of whom was schizophrenic. From an early age there were marked differences in personality. In a further investigation of

differences between identical twins, Pollin and his co-workers point out that intrauterine and birth experiences may differ, leading to constitutional but not necessarily genetic differences. Such differences may be reflected in marked differences in personality and behavior at all ages, which, in turn, may evoke different treatment from the parents. Throughout life there is a complex interplay among heredity, constitution, the interpersonal twin relationship, subsequent life events, and extrafamilial relationships.

In general, human behavior must be taken as the resultant of complex systems of factors that vary and interact in many different ways. Any assertion of cause and effect depends on a condition that is usually unstated: "other things being equal." Since other things cannot ordinarily be taken as equal, demonstration of cause and effect requires procedures like matching and randomization, supplemented by statistical tests to cancel out factors other than those under investigation within some limit of allowable error. In

real life situations there are rarely single causes, but rather a multiplicity of factors better conceived of as causal chains or networks. Changes in any portion of the network are associated with changes in other portions, and these, in turn, may affect other variables by feedback. Under such circumstances the classical definitions and demonstrations of cause and effect no longer suffice. Mathematical techniques for dealing with chains and networks are less advanced and more time-consuming. Mathematics aside, it is difficult to think in terms of networks without using simplifications that possibly vitiate the line of reasoning. An interesting example of ways in which such problems may be approached comes from the field of economics. In this area, because numerical measures are available for many variables, complex interactions can be represented by systems of simultaneous equations. It then is possible to identify a hierarchical ordering of variables, which is the basis for defining cause and effect. The procedures are formidable, but in principle it is possible by these methods to derive important conclusions about the

behavior of the real economic system even though the available information may be incomplete or approximate. Furthermore, subsystems of variables exhibit predictable degrees of stability and change within stated limits of probability.

These theoretical considerations have a bearing on the matter of schools of thought. In a multifactorial process, modification of any subsystem will produce measurable change in the system. In practice this will mean that a variety of approaches will find some support in terms of demonstrable effects. Competing theories may each find an acceptable degree of confirmation simultaneously because each affects some portion of the causal network. By directing attention to different subsystems, several investigations may be able to demonstrate what appear to be different valid cause-and-effect relationships. In the schizophrenia studies cited above the conceptual framework makes clear that there is no contradiction between

biochemical or genetic etiologies and the competing family structure and social class etiologies. Knapp proposes a similar framework for the etiology of bronchial asthma. Leighton developed a comprehensive "Outline for a Frame of Reference" of similar scope to serve as the basis for testable hypotheses in the well-known Stirling County Study. Competing schools of thought will no doubt persist until sufficient investigation establishes unified conceptual frameworks. As matters now stand, multidisciplinary studies appear to offer the best prospect toward this goal.

Models—Medical and Otherwise

Psychiatry is said by some to be in the throes of an identity crisis epitomized as a challenge to "the medical model." The challenge comes from many quarters and ranges from mild criticism to outright rejection. The sharpest attack comes from Szasz, who denies there is any mental illness, suggesting, instead, that there are only "problems of living," which are moral

and ethical, not medical. Similar criticisms of the medical model are voiced by Adams, Albee, Becker, Laing, Leifer, Sarbin, Scheflen. Somewhat less stringent criticism is offered by Cowen, Ellis, Mowrer, Reiff. Virtues and drawbacks are attributed to the medical model by Ausubel, Cohen, Crowley, Halleck, Sarason and Ganzer. Related criticisms from a sociological viewpoint are made by Goffman, Scheff, Spitzer and Denzin. Rejoinders to Szasz and the criticisms of the medical model are offered in a sequence of papers and discussions by Davidson, Slovenko, Rome, Donnelly, Weihofen, and by Begelman, Brown and Long, Brown and Ochberg, Glaser, Grinker, Kaufman, Reiss, Thorne.

Models are devices to make thinking about complex subjects easier. In a formal sense a model is an abstract logical system whose elements correspond to a set of events or things in the real world. If this model is well chosen it may be possible to perform "thought experiments" with the model and draw conclusions that might not be feasible with the real system in the

external world. There are also dangers. The usefulness of a model depends on the degree of correspondence between its elements and the "real" system in the external world. Valid conclusions can be drawn only to the extent of such correspondence. In other respects the model may not behave like the "real" system at all. In the discussion of schools of thought in the preceding section of this chapter the economic system was "modeled" by systems of simultaneous equations. It must be determined empirically how well the model corresponds to the real economic system, and transpositions from model to reality must remain within these limits. Several steps may be involved in using models. Light may first be compared with (modeled by) waves in a real medium (water or air), or the atom is modeled by electrons revolving around a nucleus after the fashion of the solar system. Then a mathematical model is devised to represent the properties of waves or rotating bodies.

It is clear that the medical model being criticized is not of this formal variety. The term is used to describe the explanation, mechanism, or process involved. The challenge is to the medical model. Is there such a model, one model that can properly be labeled the medical model?

Concern with illness is evidently as old as mankind. Explanations and theories about causes and what the process consists of have reflected the state of knowledge in each historical period. Primitive peoples could conceive only of processes that they themselves experienced directly. A man could inflict pain, so pain of unknown origin was attributed to spirits or demons. The medical model consisted of anthropomorphized creatures of the primitive imagination. The Greeks attributed illness to excesses or deficiencies of the four humors, or to excess blood. Galen left a theory of natural spirits, vital spirits, and animal spirits that survived through the Renaissance, gradually giving way before the advancing knowledge of

anatomy, physiology, and chemistry following the Renaissance. During the seventeenth and eighteenth centuries there were several medical models: (1) iatrophysics—the body conceived as a machine operating in accordance with the principles of physics and mechanics then being elucidated; (2) iatrochemistry— based on investigations of acids, alkalis, and fermentation; (3) vitalism—the living body is governed by special laws of its own, not those of the chemistry and physics of inanimate objects. Bloodletting was widely employed by all, along with numerous herbal folk remedies. Cellular pathology and the role of microorganisms became the medical model of the latter half of the nineteenth century. Subsequently other facets were added: toxins and antitoxins, immune and hypersensitivity reactions, allergies, autoimmune reactions, nutritional deficiencies, and more recently, enzyme defects. Many general principles have been formulated: patterned reflex reaction, host resistance and defense, homeostasis, generalized stressors (Selye) to name a few. As infectious diseases have receded in frequency, the

emphasis has been shifting to neoplasia, to "wear and tear"—the processes of aging and degeneration, and to the external circumstances of life and psychological stress. If from this overview a medical model can be discerned, it would seem to be merely that the processes and mechanisms of illness are to be investigated, using previous information as fully as possible but advancing to whatever new views are justified by the facts discovered.

The major criticisms of the medical model are directed against specific features attributed to that model and may be summarized as follows:

1. The medical model assumes the existence of a disorder of the mind that is like disorders of the body. Brain pathology produces specific neurological disorders, but psychiatry deals with functional disorders in which no structural or chemical alteration has been demonstrated. It is usually asserted that mind is not an organ and in principle cannot be reduced to chemical, electrical, or other physiological processes.

2. The locus of the disorder is within the affected person, and the

disorder is to be corrected or removed by the physician as is the case with known diseases of the body. This is misleading because the real locus of the disorder may be, and usually is, outside of the individual, in the social system or his interaction with the social system.

3. The medical model fosters a superior, authoritarian attitude in the physician and a dependent, subservient attitude in the patient. Both are antithetical to successful treatment, which requires that the patient achieve a greater degree of independence or autonomy.

4. Not only are there no demonstrable structural or physiological changes, but also there are no objective criteria for disturbed behavior. Mental illness can only be inferred from behavior that the illness is then supposed to explain, an obvious circularity in reasoning. Furthermore, judgment of behavior is subjective, tied to the value systems of the culture and open to various kinds of bias.

5. Because it depends on deviation from some norm, the medical

model fosters conformity and stifles originality and creativity.

Some corollary criticisms may be added. The medical model focuses on pathology that is to be removed rather than on growth, development, and maturation. Many aspects of disordered behavior are not deviations from a norm, but rather normal responses to external conditions. Pathology should be ascribed to these external conditions, not to the individual reaction. The medical model requires vast numbers of highly trained personnel to deal with existing problems. Adequate care for all who need it cannot be attained within any foreseeable time; the model must therefore be replaced.

Leifer and Szasz carry the argument further. In their view a psychiatric diagnosis is intended to derogate and destroy anyone who deviates from accepted societal norms. Once labeled, the patient is stigmatized and victimized while the power and prestige of the psychiatrist are enhanced.

Szasz's objections to the medical model begin with the definition of mental illness. His experience is that at best mental illness is a metaphor that likens personal unhappiness and socially deviant behavior to symptoms and signs of bodily ailments. Signs and symptoms are caused by specifiable disorders of bodily organs, which can be stated with some precision in anatomical or physiological terms. Disorders of the brain cause neurological defects. But the term "disorders of the mind" refers to a false substantive, mind, which cannot be a cause. Personal unhappiness is subjective and cannot be stated in precise terms. These definitional and philosophical issues are significant but not crucial. Psychiatry may be quite adequately defined without reference to mind, and many textbooks do not use the term, or if they do, specify that it is a collective designation for certain functional activities of the organism rather than a metaphysical entity. Although Szasz states that he rejects the ancient body-mind dualism in favor of a hierarchical scheme of levels of integration, his argument treats mental illness as a metaphysical

entity and thus appears to resurrect the philosophical dilemma.

A related aspect of the metaphysical problem is the contention that one cannot "have" a mental disease in the sense that one can "have" diabetes. (The quotation marks indicating special meaning are terms of the critics.) The argument is that diabetes refers to an entity that is "real," while mental disease does not. What is at issue is the meaning of terms like "have, entity," and "real." "Entity" is a metaphysical abstraction usually used to designate a hypothetical property separate and apart from the tangible and experiential aspects of an object. It is an abstraction that has meaning only as a part of a philosophical system that postulates the existence of such properties. Diabetes is not an entity in this sense. Diabetes designates a class defined by certain characteristics. A class name is neither real nor unreal; it may be more or less useful. Whether a class corresponds to anything in the "real" external world is an epistemological problem. A person does not "have" diabetes in the

sense of possessing a material object. Saying a person has diabetes merely places him in the class of individuals who show certain defining biochemical characteristics. The class falls within the larger class of diseases, which are defined as states of discomfort and/or impairment of function. There is no logical necessity to restrict the range of discomforts or impairments to be included, although the nature and basis of the discomfort or impairment are legitimate subjects for investigation. In common usage the class of discomfort or impairment is extended beyond the individual. Thus the dictionary definition of disease includes "a derangement or disorder of the mind, moral character and habits, *institutions,* the *state,* etc." Physiological alterations or the mechanisms of the signs and symptoms are characteristics added to the definition of specific diseases as knowledge about them expands. Diabetes was recognized as a disease and named 011 the basis of one of its conspicuous and easily observable features long before there was any information about its pathological physiology. In other instances older

descriptions had to be revised and new classifications added to accommodate newly acquired knowledge. Some behavioral aberrations that are today called mental diseases were recognized and described as far back as the period of classical Greek antiquity. Szasz proposes that these aberrations be renamed "problems in living" because of restrictions that he believes should be imposed on the category "disease."

The crucial criticism of the medical model focuses on deviancy. The outline of the argument is deceptively simple. Deviancy is a departure from a norm. Norms are either evaluative or statistical. If evaluative, they are arbitrary, culture-bound, and probably biased to reflect a predominant ideology. If statistical, then the distribution of any trait will have extremes, and it is illogical to label the extremes as abnormal. Careful review of the extensive writings of Szasz and the other critics of the medical model reveals several additional elements implicit in the argument. The most important one

is that nothing other than a departure from a norm is involved. Mere deviancy, without further qualification or limitation as to its nature, is said to call forth a social reaction of rejection that is institutionalized under the pseudoscientific label of mental illness. It is difficult to accept this very general thesis. Only certain aberrations are labeled in any particular culture. In Szasz's view the problem of mental illness is the right to be different in the face of societal demands for conformity. This view involves at least two further assumptions: (1) social roles and behavior are imposed against an inherent resistance; (2) conformity or nonconformity is the only relevant dimension and nonconformity is more desirable. Similar views are expressed by Leifer, Parsons, and Scheff, Laing regards psychoses as a superior and creative nonconformity in response to pressures of living in a world he considers irrational.

This line of argument has great appeal. It is addressed to the established

tradition of individuality and freedom of expression. It takes advantage of the difficulty of arriving at a satisfactory definition of mental illness, which has vexed even those who accept the concept. It invokes images of arbitrary and capricious restrictions by malevolent control agents, the institutional psychiatrists.

This line of argument is open to question on many grounds. It represents a very incomplete statement of the problem of normality and abnormality in the medical model. Mere deviation from norms does not constitute disease; rather it calls for attention and further investigation into the significance of the deviation. The precision associated with bodily disease has to do only with measurements of certain indicators of physical processes. Norms for judgment are not different in principle from those applied in many psychological processes. To take the example of diabetes again, the measurement of blood sugar is precise and objective. The dividing line

between normal and diabetic is arbitrary. It is based on the relative

probabilities that particular levels of blood sugar will be associated with the

other alterations characteristic of diabetes. If the blood sugar is near the

arbitrary borderline, judgment may be difficult and additional information

may be required. In behavioral deviation the case is not different. Certain

gross aberrations have been regarded as abnormal, while lesser aberrations

may fall into the area of uncertainty. The final judgment is made on the basis

of additional information—for example, whether behavioral deviation is

associated with changes in mood or thinking processes or whether it is

functionally disabling. Deviations are judged in the context of such other

indicators and with due regard for background factors such as culture.

The medical model does not take all hallucinations as indicators of

schizophrenia any more than it would take all elevations of blood sugar as

indicators of diabetes. In a culture where hallucinations are accepted and

even approved, the occurrence of hallucinations will not necessarily indicate psychosis. Yet it is possible in such a culture to make a judgment about pathology even though in specific instances the case may be borderline. The most stringent critics of the medical model seem on the whole to be describing individuals who exhibit minor deviations and give little evidence of subjective distress. An adequate model, however, must include those who are severely depressed, markedly agitated, or paralyzed by irrational fears.

Another major objection to the medical model is that it is based on conditions in which there are demonstrable anatomical or physiological alterations. On the other hand, psychiatry is for the most part concerned with the so-called functional disorders in which no consistent physiological changes have as yet been found despite many investigations. Invoking the concept of levels of integration, the critics contend that psychological processes by their very nature can never be "reduced" to a physiological level.

Yet, unless one accepts the possibility of a nonmaterial spirit, psyche, or mind, psychological processes must in some way be connected with, and not separate from, the physiological level. The nonreductionist position can only be accepted as an assertion of belief subject to revision in the light of further investigation. Consider an individual who arrives at the incorrect conclusion that two plus two equals five. The error may be due to ignorance or mental defect. Suppose these causes are excluded and the error persists for reasons that are not known but are presumed to be "psychological." The nonreductionist position would hold that these psychological reasons comprise the full description of the error within the appropriate level of integration. Recent investigations by John indicate that there are demonstrable differences in the electrical activity of the brain when correct and incorrect choices are made. It is possible also to demonstrate electrical patterns associated with "psychological" processes like stimulus generalization and abstraction. If such studies can be extended, it may be

possible to resolve the reductionist objection and arrive at physiological measures for normality and abnormality in psychological functions.

Many critics of the medical model assert that it fosters superior, authoritarian attitudes in physicians and dependent, subservient attitudes in patients. No doubt there are physicians and patients about whom these assertions are correct. As a generalization, however, more tangible evidence would be required than is now offered by the critics. As the matter stands, the argument is an appeal to prejudice. Patients arc given "orders" by their physicians, and they "depend" on his technical knowledge and skills. But "orders" and "depend" in this context do not have the pejorative meaning ascribed by the critics. Authoritarianism or dependency are individual qualities in no way inherent in the medical model and not necessarily characteristic of patients or physicians. Szasz holds that the medical model obscures moral and ethical problems that must be confronted. There is no

reason to believe that his position is any less likely than the medical model to foster attitudes of superiority.

A major objection to the medical model is that it requires facilities and personnel far beyond what could conceivably be made available in the foreseeable future. A new model must therefore be developed. What alternatives are offered?

Mowrer suggests that the concept of sin has been too hastily excluded. Better sin than sickness in his view. If the responsibility for sin is acknowledged there is at least the prospect of redemption. Szasz does not propose any specific alternatives. He insists that all involuntary treatment and hospitalization be abolished, but is silent about what is to be done with those now under care. Presumably he anticipates that they can all be returned to the community; therefore, he does not attempt to devise any other program. For a select few he offers an austere and forbidding version of

psychoanalysis he names autonomous psychotherapy. Most of the other critics refer in general terms to nonmedical psychotherapy, group therapy, day and night hospitals, behavioral and conditioning therapies, and a variety of environmental services. Albee, among the staunchest critics of the medical model, acknowledges the magnitude of the problem of providing such personnel in sufficient numbers. His proposal is a social learning theory of mental disorder.

> Once it is finally recognized and accepted that most functional disorders are learned patterns of deviant behavior, then the institutional arrangement which society evolves to deal with these problems probably will be *educational* in nature. ... It is quite possible that they will be combinations of present day-care centers recast as small tax-supported state schools with a heavy emphasis on occupational therapy, reeducation and rehabilitation. ... It will take several generations, perhaps a century, to replace the illness model . . . (pp. 71-72.)

Albee's new institutions are strongly reminiscent of ideal hospitals

envisaged by psychiatrists save only that he omits all mention of medication or other treatments. Elsewhere in his writings he has already dismissed all biochemical, neurophysiological, and genetic factors as irrelevant. Surely this is too one-sided and premature a view to serve as the basis for professional or public policy in the mental health field. In any event the personnel and financing required would hardly be less than under the medical model.

The most general alternative to the medical model is the social model, which attributes the major portion of mental illness to the impact of social and economic factors. This viewpoint is more concerned with prevention than with caring for those now afflicted, although there is reasonable ground to expect that improvements in social and economic circumstances might assist current patients by reducing the rate of recurrences and rehospitalizations.

What conclusions can be drawn from this overview of the challenge to

the medical model? What is *the* medical model? On the whole it appears that the medical model is whatever critics attribute to it. The model used by most psychiatrists accepts the notion that the disability of the mental patient is real and represents a dysfunction, but is not specific about the nature of the dysfunction. The concept of cause in the mental realm requires redefinition and will probably turn out to be a complex network of factors. The medical model does not require that treatment be directed internally even if the dysfunction is within the individual. Treatment can be directed at alteration of external circumstances or can consist of combinations of modalities. These are matters for investigation. Given the present state of knowledge, most of the alternative models offered represent hypotheses subject to investigation in experimental or pilot programs. The most urgent need is for a truly comprehensive model. The closest approach at this time is the kind of formulation for schizophrenia offered by the researchers at the National Institute of Mental Health.

The Future of Psychiatry

If assessment of the present status of psychiatry is subjective, time-bound, and difficult, what can be said of the future? Probably the surest prophecy is that today's speculations will soon prove to be an acute embarrassment, for history seldom moves as predicted. On the other hand, plans for the future are necessary, and some risk must therefore be undertaken. Prediction is so much a matter of personal evaluation that I will in this section depart from the customary style of handbooks and use the pronoun "I." I will attempt to anticipate the future in three time spans—near, intermediate, and long range—and three aspects —theory, education, and delivery.

For the immediate future I believe psychiatry will have to be primarily oriented to the sudden expansion of demand engendered by the extension of health care to all segments of the population under some form of insurance.

At this time there is some official hesitation about providing psychiatric services because of the anticipated high costs. Ways will have to be devised to supply the needs, and individual psychiatrists and professional organizations will have to take on roles of active advocacy. It has already been demonstrated that short-term (not brief) ambulatory treatment is insurable. Further explorations are under way. An essential feature of any system of care will be provision of a full range of services and employment of all forms and modalities of treatment. Psychiatrists must resist efforts to limit services to the least expensive treatments. The aim must be to provide a basis for evaluating the relative efficacy as well as the range of applicability and limitations of different treatments. Heretofore the distribution of treatment has followed economic lines. Only when the various modalities are available to all regardless of economic status will it be possible to determine the indications for each modality. Evaluation of formal treatments will also have to be correlated with the effects of environmental measures, such as

improved housing, education, recreation, and social services generally, to help determine their relative influence.

Theory must play a dual role. On the one hand, theory must supply clues for new approaches. These, in turn, will modify and enrich theory. The outcome should be in the form of "unified" theories, drawing upon all levels of integration, as illustrated by the work of the NIMH group previously cited. The most active development should be on the biochemical-neurophysiological level and on the social psychiatry level.

Psychiatric education will have to undergo the most drastic change. I foresee several interrelated pressures. The first is the already discussed challenge to the medical model. The overall impact of this trend has been to move psychiatry away from the rest of medicine. The outcome will depend on the competition between psychotherapies, behavioral therapies, and environmental modification, on the one hand, and chemotherapies, on the

other. The results of this competition will not emerge early, carrying the issue

into the intermediate time span. In the meantime there will be mounting

pressure from the various subprofessions to achieve independent status. An

example of this trend is the move toward autonomous schools of

psychotherapy, which will no doubt be accompanied by corresponding

professional organizations. The new categories of mental health workers, the

indigenous paraprofessionals, will undergo increasing professionalization

with gradually increasing educational requirements. At the same time some

psychiatrists and associated workers in the basic sciences will be pursuing

their investigations.

I see in these various anticipated lines of development a trend to

fragment rather than to unify the mental health field. Specialization, I believe,

is inevitable, yet the need is for integration. A possible solution is to move in

the direction of institutes of behavioral science rather than toward

autonomous schools of psychotherapy, social work, or psychiatry. These institutes would be the base for both clinical and research activities and should be located within a university that has a medical school. The core of such institutes would be departments of psychiatry, psychology, and social work, that is, the disciplines most closely involved in treatment. Each institute should also be a major center for research and should include departments of biochemistry, neurophysiology, and experimental psychology, as well as psychoanalysis and the behavioral and conditioning therapies. In addition to the foregoing, the behavioral science institute should have strong representation from anthropology, sociology, political science, economics, and social psychology.

In an institute organized along these lines the major subdivisions would probably be around treatment and research, but the unified framework would help minimize the current coolness between clinicians and researchers

so often encountered. The department of psychiatry would still be concerned with the overall integration of activity and information aimed at treatment, and would centralize and coordinate the delivery of services and evaluation of efficacy.

The relationship of the department of psychiatry to the medical school requires separate attention. If both the medical school and the behavioral sciences institute are based in a university, the pressure to separate psychiatry from the rest of medicine will be minimized. But I also foresee changes in medical education, which is also beset by the trend to specialization and the need for integration. Several medical schools have already introduced a system of "tracks." This arrangement groups the preclinical sciences and basic general clinical training in the first two to two- and one-half years. The student can then choose a track leading toward specialization or continue his general medical training. Psychiatry is one such

track. If this track could be located in the institute of the behavioral sciences, interested medical students would have early access to all the disciplines relevant to psychiatry, such as psychology, anthropology, and sociology, and could at the same time maintain their connection with the rest of medicine. Other students in the behavioral sciences institute might find their primary base in one of the related disciplines and take clinical work in the psychiatry track. The content of the M.D. degree may also change. Ph.D.'s arc now granted in a specific discipline. The trend toward earlier and more intensive specialization may lead to an M.D. in a specialty—M.D. in surgery or gynecology and obstetrics—or perhaps the M.D. will be the basic medical degree, to be followed by a Ph.D. or Doctor of Medical Science in a specialty if desired. A major advantage of a behavioral institute is that it would promote adequate comparative studies and facilitate mutual enrichment of information.

These changes in medical education will certainly not be completed in the immediate future, but will extend into the intermediate time span.

The intermediate term should see the resolution of many current uncertainties. The delivery systems should be functioning with relative efficiency and the roles of the various professionals should have been clarified. Indications for different treatments should be well established and etiological factors should be more accurately defined.

Predictions for the long term are, I am afraid, mainly affirmations of faith. I therefore affirm my belief in the ultimate perfectibility of mankind, at least to the point that men will be able to live harmoniously with other men. I see no basic antithesis between instinct and civilization, so I do not believe that either analyses or psychiatry are interminable. We do not yet know whether some individuals may be so predisposed, say to schizophrenia or manic-depressive disease, that no amelioration of societal pressures will

spare them from their disease. If in the intermediate term this should prove

to be the ease, I do not doubt that ways will be found to improve the genetic

stock of the race. When all this has been done, then perhaps psychiatrists will

no longer be concerned with mental diseases but only with problems of living.

The Genetics of Man in Health and Mental Illness

John D. Rainer

In no branch of medical science have there been more rapid, more significant, and more fascinating advances in recent years than in the understanding and application of genetics. Once the research tools and conceptual frameworks became available, psychiatry, too, finally accepted genetics as one of its foundation stones. Gene-borne and gene- external influences can now be more readily conceived as continuously interacting in human development rather than as mutually exclusive, and the study of the machinery, the processes, and the consequences of this interaction can now be seen as essential to the understanding, the control, and even the treatment of psychiatric disorder.

In the interdisciplinary setting of modern psychiatry, genetics may be thought of as an area on a map surrounded by the research fields of biochemistry, pharmacology, physiology, experimental psychology, and ethology, and the clinical pursuits of diagnosis, treatment, community and

social psychiatry, and developmental and psychodynamic understanding. In the past decade and a half, major advances in cytological and molecular genetics have captured the imagination of psychiatrists and suggested a basis for the possible mechanisms of genetic influence. New approaches to the study of the genetics of behavior have provided data on strain differences in species from drosophila to dogs, and problems of population growth and ecology have drawn attention to crucial aspects of population genetics, evolution, and the human gene pool. Meanwhile, clinicians have become more aware of individual differences in patients of all ages, in the genetic aspects of family patterns, and in hereditary differences in metabolism and response to drugs. All of these developments have opened the borders on the map described above and have made for productive communication and cooperation between genetics and the other basic and clinical sciences in psychiatry.

This, of course, was not always the case; the nature-nurture controversy, which still smoulders and breaks out occasionally, divided behavioral scientists into biologically and psychologically minded groups, and heredity and environment were thought of as separate and distinct forces. In the United States oversimplified views of one side or the other prevailed, with psychogenic or environmental forces usually given the dominant role. The behaviorism of J. B. Watson and the psychobiology of Adolf Meyer emphasized the role of external forces in molding behavior and life style; and

in the transfer of psychoanalysis from Europe before and after World War II, the attention of Freud and Ernest Jones to inborn differences was largely ignored. A few psychoanalysts of that generation preserved the unitary approach; Hartmann studied inborn characteristics of the ego, and Rado considered psychodynamics to be established on the bases of genetics and physiology. In clinical psychiatry a few American family and twin studies of the major psychoses were reported by Rosanoff, and Pollock and Malzberg in the attempt to assess the genetic contribution, but it was the publication in 1938 of Franz Kallmann's *The Genetics of Schizophrenia*, based on his Berlin family study, and in 1946 of his paper "The Genetic Theory of Schizophrenia," based on his New York State twin investigation, that for a while divided and then aroused American psychiatry to the importance of genetic factors. During his influential career Kallmann devoted his attention to many areas, including schizophrenia, manic-depressive psychosis, homosexuality, mental deficiency, aging and longevity, tuberculosis, early total deafness, cytogenetics, and genetic counseling.

Throughout the description of the various applications of genetics to psychiatry, it is well to think of the influences and interactions as taking place developmentally in time at various levels of biological organization; the atomic and molecular, the cellular and systemic, the metabolic and neurophysiological, the psychodynamic, the familial, the demographic, and the social. The psychiatric status of the organism at any given time is defined

by its interaction with its surroundings, with an interplay of effective forces whose various loci are genes, chromosomes, cytoplasm; enzymes, hormones, metabolites; brain and nervous system; infectious and toxic agents and diet; parents, families, groups, and society. In the largest sense the aim of psychiatric genetics as a scientific approach is to understand and control the etiological mechanisms both in psychiatric illness and in normal, adaptive behavior.

Interaction of Genetic and Experiential Determinants

Before any details of basic genetics or clinical application are presented, it is of prime importance to consider the problem of illustrating, conceptualizing, and describing the interaction of all types of molding forces, and in particular that between the information carried by genes and chromosomes and that provided by the natural and man-created environments. The activation or repression of genes or entire chromosomes, so obviously important in providing for cell differentiation and smooth physiological function in response to the needs of tissue and organism, is being seen more and more in terms of feedback-interaction; one model is provided by the mechanism of regulator genes outlined for bacteria by Jacob and Monod, another by hormonal control. Another example of orderly interaction at the molecular level is the production by the cells of a specific antibody in response to antigenic stimulation; less adaptive, at least to the

individual, are environmentally induced gene mutations or chromosome breaks, or disruption of genetic function by viral intrusion.

At the other extreme on the scale of time and number, the mechanisms of population change and evolution are being carefully reevaluated; positive and negative selective forces in the environment, the workings of chance, and the complexity of the genetic structures of the individual and the population, all contribute to the dynamic patterns of adaptation and change.

These various basic mechanisms, by no means completely understood, but essential to the very substance of modern genetics, can make it easier to conceive of the way genetics may function in individual development and psychopathology by serving as prototypes in some kind of general systems approach. If interaction is more than co-action, the need for two forces to combine, but rather a unique process with mutual feedback, spiral development, and critical stages, proper language must be found to describe the interworking of genetic and nongenetic factors as they come to light. Meanwhile, a few examples of clinical efforts in this direction may be presented.

Psychodynamics and Genetics

The science of psychodynamics has been considered by many psychoanalysts to be part of a total biological conception of man. In Rado's

scheme, for example, by the psychodynamic approach to an understanding of motivation and emotional control, it was considered possible to describe behavior problems and character disorders that would require for their complete explanation investigating the role of genetic transmission. Such an approach was certainly implicitly and explicitly formulated in the writings of Freud, who considered both the constitutional and accidental causes of neurotic disease, and who spoke of primary congenital variations in the ego and in the defense mechanisms an individual selects. Hartmann also, as part of his interest in twins, wrote of personality structure as the result of interaction between heredity and environment. He considered character anlagen that differentiate into character traits in the course of development, and he felt that twin studies might throw light on the possible substitution of one trait for another. Genetics may thus act as a unifying principle in future psychodynamic work, providing an opportunity to recognize fundamental genetic differences among individuals and to correlate these differences with various forms of developmental interaction.

Studies of Infants and Children: Reaction Patterns

As science progresses by the interplay of theory and observation, new formulations in ego psychology go hand in hand with fresh approaches to investigation. Verifying the observations of almost any mother, child psychiatrists have turned their attention to individual differences among

children, found them to be as important as maternal attitudes in shaping subsequent behavior patterns, and begun to study the details of the interaction in a longitudinal framework. As Anna Freud wrote, "inherent potentialities of the infant are accelerated in development, or slowed up, according to the mother's involvement with them, or the absence of it." The individual differences have been measured in various areas, among them sleep, feeding, and sensory responses, activity and passivity, motor behavior, and specific reaction patterns. Thomas, Chess, and Birch have identified nine temperamental qualities in early infancy that tend to persist at least during the first two years. These are activity level, rhythmicity, approach-withdrawal, adaptability, intensity of reaction, threshold of response to stimulation, quality of mood, distractibility, and attention span and persistence. Various psychophysiological studies of neonates have also provided pertinent data.

The role of heredity in determining these constitutional variations requires further clarification, since the interaction process begins from the moment of conception and prenatal and perinatal influences come into play as well. Refined observational techniques coupled with methods of genetic analysis discussed below can be expected to clarify this intricate matter.

Interaction Models in Psychosomatic Disorders

The principle of the interlocking effects of genetic, nurtural, and social contributions in psychopathology is well illustrated in Mirsky's studies in the etiology of peptic ulcer and Spitz's formulations regarding infantile eczema. In the ulcer studies both neonates and healthy older persons were noted to vary in the degree of secretion of pepsinogen, as measured in urine and blood; this variation appears to be genetically determined. Under conditions of environmental stress, army training, for example, a large number of those who were rated as hypersecretors developed signs and symptoms of a duodenal ulcer, but none of those in the hyposecretor group did. In Mirsky's formulation infants who are genetically hypersecretors have intense oral needs that are insatiable by the average good mother; the mother is therefore perceived as rejecting, the dependent wishes persist, and they can be revived in later life when fears of the loss of security are mobilized by environmental stress. The resultant anxiety, by pathways as yet not certain (hypothalamic, autonomic; hyperexcretion of pepsinogen, hyperchlorhydria, hypermotility, hyperadrenalism), may precipitate the ulcer in the predisposed individual.

Similar observations were made by Spitz on a group of infants institutionalized along with their unwed mothers. The infants who developed eczema differed from those who did not in a congenital predisposition and in a psychological factor originating in the mother-child relation. In particular, the infants who would develop eczema in the second six months of life showed a heightened set of responses at birth in the area of cutaneous

reflexes. Psychologically their absence of eight- month anxiety meant to Spitz a retardation in affective development and led to the discovery of manifest anxiety and repressed hostility on the part of their mothers. The mothers did not like to touch their child or care for them, deprived them of cutaneous contact, and therefore refused to gratify the very need that already at birth had been shown to be increased in this group of infants. The pathways to the actual somatic lesion are again not clear, but the model for interaction provides the new kind of dynamic role for genetics in psychiatric thought.

Molecular Chemistry of Genetics

Classical Transmission Genetics

The rediscovery of Gregor Mendel's garden pea experiments at the turn of the century established the fact that single hereditary traits are determined by paired particles (later called genes) that are unchanged throughout life, independently separate during gamete formation, and are transmitted via the ovum and sperm respectively to combine again in the zygote. The sum total of the genetic constitution of an individual, as thus established in the zygote and duplicated in every somatic cell, is referred to as the genotype, and his appearance and physiological state at any given time as his phenotype. It is possible for an individual to receive the same (or an essentially indistinguishable) gene from each parent at a given locus, and under proper

environmental conditions such a homozygote will exhibit the characteristics associated with the action of that gene. On the other hand, each parent may contribute a different gene (allele) at the given locus; such a heterozygote may exhibit traits intermediate to those associated with the homozygote for either gene, or he may display the same trait as a homozygote, in which case the trait is known as dominant. A trait that is not expressed in an easily discernible fashion in a heterozygote is known as recessive. A mutated gene arising with predictable frequency in the population, if not immediately lethal, will usually have a pathological effect expressed against the genetic background of many other factors. If dominant it will be transmitted in pedigrees in the direct line of descent through the affected parent in each generation, appearing in approximately 50 percent of that parent's offspring. Recessive traits require inheritance from both parents, who, since they are usually heterozygotes, are rarely affected themselves. A child of two heterozygotes has a 25 percent risk of being a homozygote and of being affected under usual environmental conditions. While heterozygotes, or "carriers," for a given gene are relatively frequent in the population, the chance of two such individuals mating under conditions of random choice is much less common; when the gene is rare, many of such matings will be represented by consanguineous marriages. Transmission of the gene is chiefly along collateral lines, from heterozygote to heterozygote.

Since a gene produces a given trait only via a long series of steps that

may be modified at every level by both prenatal and postnatal environmental forces and requirements, as well as by the action of other genes, the effects described above may vary from complete expression to total lack of penetrance. In many traits, particularly in variations within the range of normalcy in such characteristics as height or intelligence but also in graded pathological syndromes, the genetic contribution is made by the resultant effect of many genes, either all having minor intermediate effect (multifactor inheritance), or modifying the effect of single major genes.

Replication, Transcription, and Translation

For a half century this empirical body of knowledge was related to what was known of chromosome structure and processes of cell division, to inborn errors of metabolism, to the study of mutations, usually radiation-produced, and to the experimental, mathematical, and statistical investigation of populations and evolutionary processes. In the 1950s a new level of understanding was achieved through major advances in molecular genetics and cytology. For some time it had been known that the genetic material transmitting information from generation to generation was deoxyribonucleic acid (DNA). In 1953 the structure of this molecule was determined by Watson and Crick. Two sugar (deoxyribose)-phosphate-sugar chains are twisted about each other, forming a double helix. To each sugar is attached a nucleotide base—a purine (adenine or guanine) or pyrimidine

(cytosine or thymine). From a sugar on one chain to the corresponding sugar on the other, there is a hydrogen bond linkage that may only take place between either adenine on one chain and thymine on the other, or guanine on one and cytosine on the other. A DNA molecule may consist of thousands of such nucleotide linkages. Replication of the DNA molecule during cell division preserves the sequence of nucleotide bases, since separation of the strands, breaking the linkages between the nucleotides, is followed by the construction by each half of a new sister chain, with the sequence complementary to the original half chain. There result two double helical chains, each identical to the original. This model made possible an unparalleled explosion of investigation and knowledge.

The importance of the base sequence in the DNA molecule was soon realized, as the process of protein manufacture by the cell was elucidated. In very schematic form the code represented by the sequence in the double helix is transcribed to a single stranded molecule, messenger ribonucleic acid (mRNA), which is then found in the cytoplasm attached to structures known as ribosomes that move along its length. Here the code is translated, directing the sequence of amino acid assembly into a polypeptide chain. In this process specialized molecules of soluble or transfer RNA (sRNA) carry one by one in turn specific amino acids to specific codons, sequences of three nucleotide bases that code for one amino acid alone. Once formed, the chain assumes the spatial configuration of a specific protein molecule.

Mutation

Gene mutations represent a change in the genetic instruction. In the light of the above scheme, they arise from a change in the nucleotide sequence in the DNA, an error during replication possibly resulting from the action of certain chemicals or from radiation. This change will affect the transcription-translation process so that a modified polypeptide or protein will be produced. Since this product is either an enzyme or a structural protein such as hemoglobin, the result may be disordered function or structure—for example, the loss of enzyme activity responsible for phenylketonuria, or the altered hemoglobin structure found in sickle-cell anemia.

Control of Gene Action

In the normal functioning of the above process, it is obvious that there must exist some method of control or regulation. With every cell containing the same genes, some of these must be inactive, their message never transcribed, to account for the differentiation of cell functions. In all cells there must be some feedback mechanism whereby the production of enzymes and other products is regulated at any given time according to the needs of the entire organism. There are various theories to account for such control. Jacob and Monod have studied the action in bacteria of regulator genes whose

products may switch on or off the action of structural (enzyme-producing) genes depending on the presence or quantity of the substrate on which the given enzyme acts, or the end product of such action. In this operon theory genes are responsive to their surroundings; this is the most basic example of the process of interaction so central to the modern conception of genetics. In higher organisms more complex mechanisms, including the action of hormones, may play a role in the regulatory process.

Human Cytogenetics

While these advances in the molecular chemistry of genetics were being made, techniques were being developed that led to a corresponding explosion in cytogenetics, the visualization and study of human chromosomes in health and disease. As in many fields of knowledge, dramatic discoveries concerning human chromosomes followed quickly upon the perfection of new techniques. Some long-held hypotheses had to be discarded while a few careful observations came to be explained in a definitive manner.

For many decades the study of human chromosomes had been neglected. Even the number of chromosomes and the mechanism of sex determination had been matters of controversy. For a long time most textbooks perpetuated the erroneous statement that the diploid number of chromosomes in man was 48. It was known that females had two X

chromosomes and males one X and one Y, but by analogy with drosophila maleness was thought to be due to the presence of only one X chromosome, insufficient to balance masculinizing genes on the autosomes. There were no satisfactory methods of correlating chromosomal or nuclear patterns with clinical abnormalities.

Sex Chromatin and "Nuclear Sex" Determination

In retrospect the first breakthrough in modern human cytogenetics occurred in 1949, when Barr and Bertram4 accidentally discovered an important morphological difference between female and male cells. Examining neurons of the cat, they found, in some animals only, a densely staining chromatin mass applied to the inner surface of the nuclear membrane. It was soon realized that it was female cats that demonstrated this nuclear chromatin. This phenomenon was then demonstrated in other mammals and in man, where from 30 to 60 percent of the cells of a normal female show the dark-staining mass, referred to as sex chromatin or a Barr body. In 1954 a corresponding sex difference was discovered in polymorphonuclear leucocytes, where an additional small lobe is found in about one in 40 cells in females and in less than one in 500 cells in males. Because of its shape, this small lobe was called a "drumstick."

Since the sex chromatin body was found in females, who have two X

chromosomes, and not in males, who have one, it was originally believed to be made up of the dark-staining regions of two such chromosomes. Later it was established that a Barr body consists of all or part of one X chromosome, one that was modified, suppressed, or partially or totally "inactivated." According to Lyon's hypothesis, this "inactivation" of one X chromosome in each cell takes place early in the development of the female embryo.

Sex chromatin determination in humans may be accomplished by examining any cellular tissue; in practice it is most convenient to study smears made of oral mucosal cells. After swabbing the inside of the cheek gently with a gauze pad, the roughened surface is scraped with the edge of a narrow metal spatula. The buccal material is spread onto a glass slide, which is fixed in 95 percent ethyl alcohol for 30 minutes. It is then washed and stained by a nuclear stain such as thionin or cresyl violet, cleared, and mounted; between 100 and 200 cells are then examined.

It was not long before the process of "nuclear sexing," as it was then called, was applied to certain cases of human infertility and abnormal sexual development. In 1954 female patients with gonadal aplasia (Turner's syndrome) were reported to be chromatin-negative, that is, to lack the nuclear chromatin body. Such females tend to be of short stature and sexually infantile, and their ovaries are reduced to streaks of connective tissue. Associated defects such as webbed neck and increased carrying angle of the

arms are often present. Occurring with an estimated frequency of 0.2 to 0.3 per 1,000 females, Turner's syndrome may include slight intellectual impairment but not severe mental deficiency. Because of the absence of nuclear chromatin, early investigators considered such patients as "chromosomal males" with some form of sex reversal. Although this interpretation was not generally accepted, it was finally corrected only by later findings, which are described below.

A second classical example of nuclear sex anomaly was Klinefelter's syndrome, characterizing males with small atrophic testes, sterility, gynecomastia, and increased excretion of gonadotropin. Occurring in about one in 500 male births, it accounts for about 1 percent of male mentally retarded patients in institutions. In 1956 a high proportion of patients with this clinical syndrome were found to be chromatin-positive; they were for a time incorrectly termed "chromosomal females," presumably with two X chromosomes. Further elucidation of the etiology of this disorder also awaited study of the chromosomes themselves and direct observation of the patients' sex chromosome constitution.

Technical Advances In Human Cytogenetics

The next set of studies in human cytogenetics followed the perfection of methods for observing human chromosomes microscopically. Earlier

investigations were done mostly on testicular biopsies, but degenerative changes as well as clumping and overlapping of chromosomes led to inaccurate counts. The introduction of tissue culture methods made available a better source of cells in the process of mitotic division, the stage in which the chromosomes are distinguishable. Treatment with colchicine arrested dividing cells in this stage, and the use of hypotonic solutions swelled the nuclei, spreading the chromosomes and separating them for examination before final staining of the cells in slide preparations. Photography under the oil immersion lens revealed the chromosomes as X-shaped bodies, each representing a single chromosome in the process of dividing. First applied to skin biopsy material and bone marrow, these techniques have been variously modified and at present are applied most practically to lymphocytes of peripheral blood.

Suspended in their plasma and stimulated to divide by the addition of phytohemagglutinin, such cells are protected against bacterial contamination by antibiotics. After three days of incubation at 37°C, they are ready for harvesting after being arrested at the cell division stage by adding colchicine or a derivative of it. The addition of hypotonic sodium citrate solution is followed by fixation, slide preparation, staining, clearing, and mounting.

Normal Human Karyotype

In 1956 these new techniques resulted in the demonstration of 46 chromosomes as the correct number in man. It became possible to study clear and easily examined preparations of human chromosomes, to photograph them, and to enlarge, cut out, pair, and mount them in order of decreasing length. Such an arrangement is called a karyotype; a diagrammatic representation thereof is called an idiogram.

Chromosomes may be distinguished from one another by their length and by the position of the constriction called the centromere, the point at which the two parts of the dividing chromosome still remain joined. The centromere may be median (metacentric), submedian (submetacentric), or subterminal (acrocentric) in location; in many chromosomes of the latter type satellite bodies may be seen projecting from their short arm.

When arranged in order of decreasing size, the human chromosomes fall into seven groups, which were standardized at a historic meeting in Denver in 1960. The groups may be clearly distinguished, and chromosomes within a group can often be recognized with a high degree of probability. In line with the system proposed at the Denver meeting, the description of the chromosomes is as follows:

Group 1-3. (A) Large chromosomes with approximately median centromeres. The three chromosomes are readily

distinguished from each other by size and centromere position.

Group 4—5. (B) Large chromosomes with submedian centromeres. The two chromosomes are difficult to distinguish, but chromosome 4 is slightly longer.

Group 6-12. (C) Medium-sized chromosomes with submedian centromeres. The X chromosome resembles the longer chromosomes in this group, especially chromosome 6, from which it is difficult to distinguish. This large group presents the major difficulty in identification of individual chromosomes.

Group 13-15.(D) Medium-sized chromosomes with nearly terminal centromeres (acrocentric chromosomes). Chromosome 13 has a prominent satellite on the short arm. Chromosome 14 has a small satellite on the short arm. No satellite has been detected on chromosome 15.[1]

Group 16-18. (E) Rather short chromosomes with approximately median (in chromosome 16) or submedian centromeres.

Group 19-20. (F) Short chromosomes with approximately median centromeres.

Group 21-22. (G) Very short, acrocentric chromosomes. Chromosome 21 has a satellite on its short arm. The Y-chromosome is similar to these chromosomes.

Further conferences were held in London in 1963, in Chicago in 1966, and in Paris in 1971, with the aim of increasing the accuracy of chromosome identification. The presence of secondary constrictions and the determination by radiographic means (incorporation of radioactive thymidine into replicating chromosomes) of the time sequence of chromosome replication were among the methods suggested at the London conference; in Chicago a standard nomenclature was adopted for describing the human chromosome complement. More recently new staining techniques were reported that promise to make each chromosome individually recognizable by disclosing banded regions; among the distinguishing characteristics are fluorescent patterns seen after exposure to quinacrine derivatives and deeply colored bands using various modifications of Giemsa staining methods.

Chromosomal Abnormalities

Within three years after the correct determination of the human

karyotype, and even before the numbering system was standardized, important discoveries were made correlating abnormalities in the karyotype and clinical syndromes. The first group of these abnormalities arose from the presence of an abnormal number of chromosomes and resulted from a process known as nondisjunction in the formation of the gamete (sperm or ovum). Instead of the two members of a given pair of chromosomes separating, each one going into a separate sperm cell (in the male), or into the ovum and polar body, respectively (in the female), they both go into the same gamete, producing two kinds of abnormal gametes, those with two chromosomes of a given pair and hence with one chromosome too many, or with none of that pair and hence one too few. When united with a normal sperm or ovum, such a gamete yields a fertilized ovum (zygote) with either 47 or 45 chromosomes in all. Similar processes of nondisjunction at an early cleavage stage of the zygote, resulting in cells with even more than 47 chromosomes, have been found in conjunction with the X and Y chromosomes. It is also possible in such cases that cells of more than one kind are formed, each one of which perpetuates its line, giving rise to individuals with cells of two or more types. This phenomenon is known as mosaicism.

The first condition found to be associated with a chromosomal anomaly was mongolism, preferentially referred to as Down's syndrome. The association of this syndrome in the preponderance of cases with children born to older mothers, and the one-egg twin concordance rate of close to 100

per cent, foreshadowed an early germinal, possibly a chromosomal, defect as the responsible agent. Early in 1959 tissue culture methods showed that patients with Down's syndrome had 47 instead of 46 chromosomes and that the additional chromosome was one of the smallest chromosomes, no. 21 in the conventional numbering system. Arising by nondisjunction (especially in the female, as is suggested by the association of the condition with advancing maternal age), the extra chromosome, small as it is, causes widespread morphological and biochemical abnormalities.

Some cases of Down's syndrome, especially those born to younger mothers or those with a familial concentration, were assumed for a while to have a normal chromosome complement. However, upon closer examination of the karyotype, one of the chromosomes of the 13 to 15 group was found to have attached to it the long arm of an extra chromosome 21. Thus there was a translocation of chromosomal material, a situation that may be transmitted from generation to generation. If two normal chromosomes 21 are present, in addition to the 15/21 translocation chromosome, the individual is affected; if only one is present, the individual is normal. In the latter case, however, he or she may be a "carrier," that is, may bear affected children, by producing a gamete with both the translocation chromosome and a normal chromosome 21. Translocations have been found also between chromosomes 21 and 22. From a practical point of view the translocation mechanism for producing this syndrome is very important. For most mothers of a child with Down's

syndrome, the chance of having a second such child is very small, hardly greater than for any other woman of the same age (1 in 600 altogether, up to 1 in 50 in mothers over 45). A mother with a 15/21 translocation has a much higher risk (about 10 percent) of having a second affected child, apart from that of having children who are carriers. If the father has the translocation, the empirical risk of having an affected child is lower (2 to 3 per cent). Microscopic chromosome examination is therefore strongly indicated in counseling such families.

Other conditions with trisomies of autosomes have been described that are rare in live-born infants and usually result in early death. One of the conditions, involving a chromosome of the D group, is characterized by symptoms that include microphthalmus, harelip, cleft palate, and polydactyly, frequently accompanied by congenital heart defects, in another, in which an E group chromosome is involved, is characterized by micrognathia, low-set ears, overlapping of fingers, and other skeletal and cardiac defects.

Abnormalities Involving Sex Chromosomes

After interest had been aroused in sexual abnormalities with anomalous chromatin patterns, it was not long before the techniques of studying human karyotypes were applied to these conditions. Chromatin-negative Turner's syndrome was found to be associated with only 45 chromosomes, one of the

sex chromosomes being missing. The resulting sex chromosome constitution was first called the XO condition, "O" indicating simply the absence of a chromosome normally present; in the Chicago nomenclature it is called 45, X. Apparently this condition may originate by nondisjunction in the formation of either the sperm or the egg. Thus, while normal sperm cells have either an X or Y chromosome (in addition to 22 autosomes), the nondisjunction phenomenon may yield sperm cells having both X and Y (XY) with 24 chromosomes in all, or neither (O) with 22 chromosomes in all. Similarly, while normal ova all have one X chromosome, the abnormal ones may have two (XX) or none (O). Fertilization of an O gamete by a normal X gamete results in the karyotype of Turner's syndrome.

In similar fashion patients with Klinefelter's syndrome are known to have 47 chromosomes with an extra X chromosome (XXY), brought about by the union of an abnormal XY sperm with a normal ovum, or an abnormal X ovum with a normal Y-bearing sperm. A third classic example of chromosomal abnormality in the human is represented by females, sexually infantile and amenorrheic, with an XXX chromosome pattern.

The sex chromatin pattern in these anomalies can now be shown to be related in a simple way to the chromosome structure. The number of nuclear chromatin patches is always one less than the number of X chromosomes found—hence Turner's syndrome has none, Klinefelter's has one, and the

triple X female has two. In terms of the Lyon hypothesis, this finding can be explained by the inactivation of all X chromosomes in excess of one. At the same time it has been established that the presence of a Y chromosome is necessary and sufficient for maleness, since the XO individual is female with only one X chromosome but no Y, while the XXY, possessing two X chromosomes but also possessing a Y, is male.

These sex chromosomal anomalies are the prototypes of more complex pictures that have been reported. Nondisjunction during later cell divisions after the zygote is formed may produce such abnormalities as XXXY or XXXXY individuals (males similar to Klinefelter's syndrome but with severe mental deficiency) and many varieties of mosaicism. It has been estimated that one in every 150 newborn infants has a chromosome aberration identifiable by present techniques.

Chromosomal Abnormalities and Psychiatric Syndromes

Aside from the importance of human chromosome analysis for diagnosis and counseling, its value in unraveling the processes of gene action is only beginning to be exploited. For one example, the correlation of specific disorders with syndromes associated with chromosome abnormalities may serve to localize the genes involved on particular chromosomes or the metabolic (enzymatic) pathways of gene action and may also help to

distinguish nosological subgroups in major diagnostic categories.

In the major syndromes of psychiatric importance chromosomal findings have been equivocal. Only a small proportion of schizophrenic patients seem to display a sex chromosome abnormality; conversely a few of the mentally defective patients with abnormal karyotype show psychotic or schizophreniclike behavior.

Klinefelter's syndrome, with 47,XXY karyotype and its variants, leads to degrees of eunuchoid habitus and weak libido, low marriage rate, often mental deficiency, and personality disorders ranging from inadequate personality and delinquency to symptoms of schizophrenia. This trisomic condition has been found three times as frequently in mental hospitals as among newborns. If this figure is upheld it will still have to be clarified whether the patients have psychotic-like syndromes resulting from the chromosome imbalance or whether the chromosomal syndrome precipitates an otherwise determined psychosis by adding an additional biological or social burden. Similar considerations apply to the extra X chromosome in the female, the 47,XXX syndrome. Once misnamed "superfemales," those who have been found in clinics and hospitals are often mildly retarded and socially withdrawn; they seem to be found more often than expected in mental hospitals, but their incidence at birth (1 in 1,000) is only a rough estimate. Schizophrenia in women with the XXX karyotype has recently been studied by

Vartanyan and Gindilis.

Turner's syndrome, typically a short and sexually undeveloped female, is associated with the absence of the second sex chromosome, leaving 45 chromosomes with a single X. If emotional reaction, sexual immaturity, and body defects play any role in the extra X syndromes described above, they do not seem to result in any disturbance here, for these girls and women have been described as resilient to adversity, stable in personality, and maternal in temperament. They are not mentally retarded except in some nonverbal skills centering about space-form appreciation and constructional skills. This finding is significant as one of the few examples of a specific intellectual correlate of a karyotypic defect.

A great deal of interest has been generated in the 47,XYY anomaly. Although noted in the general population, males with this chromosome constitution were found in seeming excess in correctional institutions where they were noted to be tall, mentally deficient, and prone to aggressive behavior patterns. The specificity of this syndrome has been questioned, especially since the frequency of XYY males in the total population is not yet accurately known.'" Fluorescent staining techniques in buccal epithelial cells should be able to provide better data both on the incidence of the karyotypic abnormality and its possible consequences in the course of development. Cases studied so far, including a pair of adolescent twins, suggest that at least

some of these men are usually passive, withdrawn, inadequate, and docile, but under stress they may exhibit impulsive behavior. There is also suggestive evidence that these periodic episodes have a seizurelike course and that the electroencephalogram may be abnormal.

Further information on the relationship between chromosome imbalance and mental symptoms may one day elucidate some of the genetic mechanisms in behavior disorders. An analogy has been provided in studies of the fruit fly by the correlation of behavioral response with contributions from specific chromosomes.

Methods of Investigation in Psychiatric Genetics

Pedigree Method

The study of individual families or pedigrees has often been used to suggest forms of genetic transmission for larger-scale investigation or to provide tentative material on rare, well-defined pathological conditions. They have to be supplemented by the study of more representative samples with proper attention to statistical methods of correcting for ascertainment.

Census Method

In geographically confined populations, small enough to be visited

individually, and with good medical and demographic records, it has been possible to study the population and family distribution of diagnosable psychiatric disorders; this method has provided some excellent reports in certain Scandinavian areas.

Family Risk Studies

An extension of the pedigree method, studies of family risk (sometimes referred to as contingency methods) have as their goal comparing the expectancy risk for a given condition in the relatives of affected individuals with that in the general population. A number of pitfalls must be avoided. The affected individuals must be diagnosed according to uniform criteria, and they must represent a consecutive series of patients (or a random sample thereof). They are designated then as index cases, or probands. All relatives in the desired categories must then be located and diagnosis made. Since one is interested not in the incidence (new cases) or even the prevalence (total cases) but rather in the expectancy rate (cases that may arise during the lifetime of the relatives), it is necessary either to wait for many years or more practically to apply a correction method. A simplified method often used is the Weinberg abridged method. A manifestation age interval is derived clinically; in schizophrenia, for example, it is usually taken at 15 to 45 years. The number of cases found among a given category of relatives (the numerator) is related to a denominator that is not the total number of

relatives in this category, but rather that number diminished by all of those who have not reached the earliest manifestation age and half of those still within the manifestation period. This method yields a risk figure, representing the expectancy of developing the given condition for those who will live through the manifestation period. This figure can then be compared with risk figures for other groups of relatives and for the general population. The latter have been determined in many cases by total or sample population studies, or by studies of the relatives of control patients.

Twin Family Method

An extension of the family risk method to families containing twins makes possible a series of further approaches to understanding the complementary roles of nature and nurture, heredity and environment.[97][98] First used by Galton, the method depends upon the occurrence of two types of twins, those derived from a single fertilized ovum that has split and developed as two separate individuals ("identical," monozygotic, or one-egg twins) and those derived from two ova, fertilized by two different spermatozoa during the same pregnancy ("fraternal," dizygotic, or two-egg twins). In the first case the twins are always of the same sex (barring a rare sex chromosome loss early in embryonic division, which may result in a pair of one-egg twins made up of a normal male and a female with Turner's syndrome). On the average dizygotic twins are one-quarter of the time both

male, one quarter of the time both female, and half the time of opposite sex. Zygosity determination can be made with a high degree of accuracy by similarity of somatic characteristics. The accuracy is further increased by comparison of fingerprints and blood groups, while immunological methods such as reciprocal skin grafting may provide certainty in individual pairs where intensive study requires and warrants such procedures. Monozygotic twins are born with the same genotype; dizygotic twins are as similar genetically as any pair of sibs.

In the twin family method the index cases are twins. Expectancy rates can be compared between monozygotic twin partners, dizygotic twin partners of the same sex, dizygotic twin partners of opposite sexes, full sibs, half sibs, and step sibs. This method provides a graded series of genetic relationships and a differently graded series of environmental ones; the extent to which the risk in the various categories of relatives corresponds to the genetic similarity bears a relation to, or is a measure of, the genetic contribution to the etiology of the condition. For example, if the expectancy in monozygotic twins is higher than that in dizygotic twins of the same sex (despite the environmental similarities) and that in dizygotic twins is close to that in full sibs (to which they are genetically equivalent), there is a measurable genetic contribution. Another way of separating genetic and environmental influences would be to study identical twins reared apart from birth, preferably in homes with disparate social and psychological settings,

but such pairs who also present a particular syndrome are rare.

There are a number of cautions and misunderstandings about twin studies to be noted. Before using the twin concordance method, it is necessary', for example, to determine that a condition to be investigated is no more prevalent in twins than in single-born individuals. In doing a study the sample of twins should be complete, with the expected proportion of monozygotic and dizygotic pairs, and the diagnosis of zygosity and that of illness should be made by separate persons without knowledge of the other's findings. In interpreting the results of twin studies, the assumption of comparable environmental patterns for monozygotic twins and dizygotic twins, at least those of the same sex, has been questioned; yet observation of twins and their families has often shown similar family dynamics and role assignment—twin dependency, parental need to distinguish, and so forth— with both types of twins. Indeed, monozygotic twins are often more disparate in size and vigor at birth than dizygotic ones. Finally it should be realized that it is not necessary to have 100 percent concordance in monozygotic twins to postulate a genetic contribution; provided they are sufficiently higher than the dizygotic rates, monozygotic concordance rates of under 50 per cent, for example, can be shown by analysis of variance techniques to indicate a high heritability value.

Co-Twin Control Studies

The use of longitudinal data from selected pairs of monozygotic twins, particularly those discordant or dissimilar with respect to the overt expression of a behavioral trait or syndrome, may serve to point out important developmental factors. Among the reported case histories of twins and other sets of persons of multiple birth, the study of Rosenthal's group on the aptly named Genain quadruplets is particularly notable because of its thoroughness and its adherence to the concept of heredity-environment interaction. Although all members of the set were found to be schizophrenic, their psychoses varied in symptomatology as well as in intensity.

Other investigations of this type include the series of homosexually dissimilar twins studied by Rainer, Mesnikoff, Kolb, and Carr. Obtaining data through psychiatric anamnesis, family interviews, and free association, these studies paid particular attention to: (1) the prenatal fantasies and wishes of each parent about the sex of the expected child; (2) the attitude of the parents toward the twins' birth; (3) the family significance of the naming, both as established before birth and as modified by the birth of the twins; (4) the parental efforts at differentiating the twins; (5) the occurrence of physically distinguishing features in the twins; (6) the emotional connotations of such features to the parents and the extended family; (7) the effect of such bodily distinctions on the differential mode of mothering for each twin; (8) the differing object relations of the twins from birth onward; (9) the attitude of each twin to his body and to his self, as perceived and as seen ideally; (10) the

fantasy life of the twins, particularly in the sexual area; and (11) the superego growth of the twins, particularly in relation to sexually allowed and prohibited forms of activity. Benjamin studied a pair of male twins concordant for asthma but dissimilar with respect to a number of important psychological features, in the context of seeking to "conceptualize most complex behaviors in terms of different sorts of interactions between innate and experiential constants and variables."

In a pair of twins concordant for the XYY chromosome anomaly, but dissimilar in the degree of control over episodic impulsive behavior, Rainer, Abdullah, and Jarvik noted the mother's search for personality differences at birth, and the occurrence of petit mal seizures in one twin at the age of three. It was suggested that these early events may have set a double pattern—focusing of the mother's concern on one twin as being psychiatrically and neurologically abnormal, and a protective and caring response on the other child's part, which helped him to strengthen his control and responsibility over himself. As in all of these studies, similarities in underlying personalities were noted, particularly in projective testing, with differences in overt behavior then attributable suggestively to patterns of family dynamics as well as to physiological differences.

In the study of identical twin pairs discordant for schizophrenia by Pollin and his co-workers, again there were physiological differences, namely,

lower birth weight for the subsequently schizophrenic twin, that directly or in interaction with family dynamic patterns may have influenced their development.

These studies help one to understand that genes actually determine a norm of reaction, the exact expression of which depends on many prenatal, perinatal, and postnatal interactions. The pathways are labyrinthine that lead in twins from the identical molecular structures that constitute the genic patterns to the manifestations in later life of behavior traits; minor shifts in the dynamic process at nodal points may lead to wide phenotypic divergence. Preconceived ideas on the locus of such nodal points should be regarded with caution. A spiral-like development toward marked behavioral dissimilarity may arise not only from postnatal influences on the twins but also in the prenatal stages of development. Infant, childhood, adolescent, and adult experiences may thereafter precipitate a single gene effect or shape the expression of a polygenic trait in a unique way.

Adoption Studies

The physical separation from their biological parents of children reared in adoptive homes offers a valuable method of weighting genetic and environmental influences. Some studies involving adopted children have compared those with affected biological parents to those with unaffected

biological parents, while others have compared biological and adoptive parents and other relatives of affected adopted children. Some of the findings in these kinds of studies are discussed in Volume Three, Chapter 25, of this handbook in connection with genetic studies in schizophrenia (Rosenthal).

Longitudinal Studies

Longitudinal studies of high-risk infants and children are of the greatest potential value in learning about the role and vicissitudes of genetic predisposition in mental illness. Since there is evidence for increased risk with greater genetic loading in a given syndrome, children of one or of two affected parents may be followed, comparing them with their sibs and with control children, searching for early behavioral, biochemical, neurological, psychophysiological, and clinical signs, for patterns of development, and for protective factors.

Other Methods of Genetic Investigation

Of course, the most direct way of establishing genetic etiology would be to identify errors in the genetic code itself; the closest available approach is through identification of a specific enzyme deficiency or modification, particularly in the brain or nervous system. This may be done by electrophoretic methods or by studying products of intermediate metabolism.

Loading techniques—tolerance tests—may make such deficiencies more obvious in the case of heterozygotes. Correlation of psychiatric symptoms with chromosome anomalies has been discussed; more subtle chromosomal changes will be detected with the perfection of new staining techniques, as well as with techniques of cell hybridization.

A method for establishing homogeneous genetic categories is the study of genetic linkage; a syndrome may be associated with the effect of a single gene if it appears to stem from a locus on the same chromosome with, and at a given distance from, the locus of another known gene. In principle linkage is suggested by the detection of pedigrees in which there is a reduced frequency of recombination between genes at two particular loci; for example, depression and color blindness, occurring in the same family, may be found usually together or usually separately.

The correlation of psychiatric syndromes with certain physical characteristics—blood types, dermatoglyphics, constitutional habitus—may be a lead to the presence of a genetic basis. Finally, in cross-cultural studies, if variations in the frequency of a syndrome across different populations are determined only by population-genetic variables, such as consanguinity, genetic drift, or selection factors, the syndrome is more likely to have a genetic basis; if, however, there are strong differences in prevalence that are determined by cultural and environmental factors and that are not due to

differences in diagnostic procedures, the genetic contribution, although it may still be present, will be more difficult to detect.

Genetics and Psychopathology

Schizophrenia

For over 40 years family and twin studies, studies of adopted children, and longitudinal studies, both retrospective and prospective, have yielded data consistent with the presumption of a necessary, although not sufficient, hereditary basis for schizophrenia. From the point of view of the present discussion, four themes may be noted in appraising this area of research today. The first is the need to define more precisely the significant genetic and environmental influences; the second is to find better ways to describe their interaction; the third is the increasing evidence that genetic determination seems to vary with the severity of the illness and to bear a relation to newly delineated clinical types; and the fourth is the emergence of longitudinal studies that promise to throw light on developmental mechanisms and the natural history of the condition.

Because of modern treatment and community care methods, the marital rates of schizophrenic patients have increased, resulting in a higher number of fertile marriages and higher overall reproductive rates; therefore, the need

for better understanding of genetic data for use in counseling and child-care programs is evident.

Affective Disorder

Studies of families and twins have played an important role in both the nosology and etiology of affective disorder. Earlier reports have focused on manic-depressive illness. In his classic investigation of this syndrome, Kraepelin observed large numbers of relatives who had the same illness, but he did not find an increase in dementia praecox among these relatives. In most European and American populations the general rate for manic-depressive psychosis varies between 0.4 percent and 1.6 per cent, though in a few special situations, such as isolated populations, rates of as low as 0.07 percent and as high as 5 or 7 percent have been found. An excess of females has been consistently observed. In the case of parents, sibs, and children of manic-depressive index cases, the expectancy rates are much higher, with a morbidity risk in first-degree relatives of about 20 percent reported in earlier studies. With both parents affected, the morbidity risk in children has been found to be as high as 40 per cent.

In the largest twin family study that has been reported, Kallmann located 27 one-egg and 58 two-egg pairs. In this series the expectancy of manic-depressive psychosis varied from 16.7 percent for half sibs to 22.7 and

25.5 percent for sibs and two egg co-twins, respectively, and 100 percent for one egg cotwins. Parents of index cases showed a rate of 23.4 percent. Since only patients admitted to a mental hospital, and hence the most severe cases, were included as index cases, the apparently perfect concordance rate of 100 percent for one-egg twins was considered an artificial maximum value. Other twin studies corroborated these data.

Recent investigations have tended to subdivide affective disorders into two subgroups, bipolar illness with periods of mania, and unipolar illness with symptoms limited to recurrent depression. Family studies conducted in these two groups have shown different morbidity risk in relatives, with the bipolar cases showing more genetic loading than the unipolar cases or than the earlier combined groups. A 34 percent risk was found, for example, in the first-degree relatives of bipolar patients studied by Winokur. Moreover, both bipolar and unipolar illness have been found in the first-degree relatives of bipolar cases, while families of unipolar probands have shown only unipolar illness.

These data seem to indicate that bipolar and unipolar illness are different with regard to their genetic component, although the nature of the genotype of the unipolar relatives found in bipolar families remains in question. Much current research is directed toward exploring further genetic heterogeneity in the bipolar group of affective disorders. Asano attempted to

delineate subgroups of manic- depressive illness on the basis of clinical symptoms, with a "typical" group showing manic-depressive symptoms in a relatively pure form, and an "atypical" group showing clouding of consciousness, or schizophrenic or severe autonomic symptoms. The typical forms were found to have a greater and more specific genetic loading than the atypical forms. Some studies have divided the group according to time of onset, with earlier onset associated with more severe genetic loading, later onset with a negative family history; while others have classified patients on the basis of their response to pharmacological treatment. In the latter category is the proposal by Pare and Mack to differentiate genetically between patients and affected family members who respond only to MAO inhibitors and those who respond only to tricyclic antidepressants. Similar studies are in progress with relation to lithium response.

Kallmann and Stenstedt favored an autosomal dominant form of inheritance in manic-depressive illness, with incomplete penetrance and variable expressivity. Rosanoff in 1934 and currently Winokur and Tanna support the presence of at least two dominant factors in the transmission of bipolar affective disorder, one X-linked, the other autosomal. Perris has supported X-linked transmission only in unipolar cases. Other investigators have reported data on ancestral secondary cases that are consistent with a polygenic hypothesis. None of these results are really contradictory, as one of the genes involved in polygenic inheritance may well be X-linked.

The X-linked hypothesis is based on the observation of an excess of females in the sex ratio of manic-depressive illness and the rarity of father-to-son transmission. Recently Reich, *et al.*reported on linkage studies between manic-depressive illness and two X-linked genetic markers—Xga blood group and color blindness.

From a psychodynamic point of view Rado described the psychological characteristics of the individual predisposed to manic-depressive psychosis as a tendency to emotional overreaction from infancy, a persistent alimentary dependent state, a strong craving for gratification from without, and an intolerance to pain. He considered the depressive spell to be the final stage of an etiological progression beginning with the genotype. Further data regarding modification of symptoms by developmental factors were provided by the New York study of persons totally deaf since birth or early childhood. Although the prevalence of affective illness did not differ from that among the normal hearing population, there was a decrease in symptoms of guilt and retarded depression, with paranoid symptoms or agitation taking their place. It was hypothesized that the tenuous nature of early object relationships played a role in this modification.

Involutional depression was considered by Kraepelin to belong to the large group of manic-depressive psychosis. Kallmann found an elevated risk of schizophrenia in the relatives of probands with involutional melancholia,

with no increased risk for manic-depresssive psychosis. He considered the syndrome to be pathogenetically complex and genetically associated more closely with the group of schizoid personality traits than with manic-depressive psychosis. Other investigators found an increased morbidity risk for affective illness in the relatives of involutional probands. These discrepancies are probably due to differences in diagnostic criteria.

Criminality

Early studies of twins involving criminal behavior suffered from sample selectivity and heterogeneity; they tended to show high concordance rates for both monozygotic and same-sex dizygotic twins. This distribution of concordance rates led genetic investigators to suspect a large environmental role in the pathogenesis of criminal behavior. Individual pairs of twins have been described with divergent overt histories, and it would seem to be more appropriate to study specific personality traits leading to a life of crime rather than criminal behavior itself. The current status of the role of chromosomal abnormalities in criminal behavior has been considered earlier in this chapter.

Intelligence and Mental Defect

There is perhaps more controversy today about the role of heredity in

intelligence than any other aspect of behavior genetics; the value of early childhood education, the nature of learning, the problem of underprivileged groups, and innumerable school policies have become involved with this issue. The question often narrows down to one of priorities in making very practical decisions. Underlying much of the divergence of conclusion is the basic difficulty of measuring intelligence apart from environmental influence. Intelligence scores, largely consisting of IQs, show remarkable correlation with genetic closeness; these similarities persist in longitudinal studies of twins, for example, and in twins reared apart since early life. It is not so clear yet what factors are measured by the various tests, or how their results are affected by such environmental factors as maternal health and nutrition, or communication and educational patterns at home and in school.

A valuable contribution to the role of communication in intelligence was made by the study of a group of 33 pairs of twins discordant for early total deafness. In these pairs the verbal IQs showed significant difference that disappeared in the performance scales. The role of emotional factors in learning, both those associated with interpersonal channels of acceptance and identification and those related to security and motivation, preclude simple formulations.

In the field of mental defect some of the data are more clear-cut. Mental deficiency syndromes based on specific gene mutations and chromosomal

aberrations are well known, although there are intelligence differences among persons with such syndromes that must be explained on other genetic or environmental grounds. According to Reed and Reed,s8 however, these specific genetic factors, together with obvious infectious or birth-traumatic incidents, account for barely half of persons with IQs below 70. These authors consider that polygenic inheritance is responsible for most of the rest, with social deprivation usually playing a secondary or modifying role. In any event they conclude that five-sixths of persons in the given lower IQ range have had at least one parent or an aunt or an uncle similarly retarded.

Aging and Life Span

In human populations there have been a number of studies relating the life span of offspring to that of their parents. In Pearl's work longevity ("regarded as a single numerical expression of the graded effects of all the forces that operate upon the individual, innate and environmental") was investigated by comparing the ancestors of two groups of persons, one a group of persons still living at 90 years and above and the other a random group of individuals. The sum of the ages at death of the six immediate ancestors of the index cases was significantly greater in the longevous group than in the comparison group.

The most extensive and carefully followed investigation of aging has

been that conducted in the Department of Medical Genetics of the New York State Psychiatric Institute since 1945 by Kallmann and various colleagues and continued at the present time by Jarvik and associates. These investigations started with 1,603 twin index cases over the age of 60 and followed the mortality patterns of 584 pairs where both twins qualified as index cases. The length of time between the death of the first twin and the death of the second twin has been consistently greater in the dizygotic pairs than in the monozygotic pairs. These studies also confirmed the relationship between the mean life span of the twins and their sibs and the age of death of their parents. The investigators felt that life span potential was demonstrated to have a genetic basis that could be assumed to follow the multifactor type of inheritance. Also studied were intrapair differences in psychometric test scores, which were larger for dizygotic than for monozygotic twins. There was some indication that stability of intellectual performance was associated with survival.

In searching for possible biological concomitants of aging, Jarvik and her colleagues undertook chromosome examinations of peripheral blood lymphocytes to determine whether there were increasing deviations from the normal chromosome number with increasing life span. Such losses in peripheral blood lymphocytes might reflect similar aneuploidy in glial cells. As compared with a group of young individuals, an excess of chromosome loss was found in the aged women but not in the aged men. The chromosome

loss among aged women was random and not limited specifically to C group chromosomes; in the aged males, although they showed no greater frequency of overall chromosome loss than young males, the chromosomes that were lost were largely in the G group.

Finally a higher frequency of chromosome loss was found by Nielsen, *et al.*, and by Jarvik and her associates in the peripheral leukocytes of women with organic brain syndrome compared with other women of comparable age. In the New York study a significant increase in the frequency of chromosome loss was found in the women who had organic brain syndrome without evidence of cerebral arteriosclerosis, compared with women without organic brain syndrome. The relationship between chromosome loss and organic brain syndrome in males, however, appeared to be purely random. In women a positive association between chromosome loss and memory loss was also demonstrated by psychological testing.

Genetics of Psychosexual Development

Intersexual Conditions

Concerning the genetic aspects of intersexual conditions, recent findings related to chromosomal abnormalities have already been discussed. Not all sexual anomalies, however, are by any means associated with karyotypic

changes. Most hermaphrodites with both testicular and ovarian tissues are found to have normal karyotypes, although some are mosaics. A few pseudohermaphroditic states, although distinguished by normal karyotypes, are apparently caused by gene-borne influences. Among them are the testicular feminization syndrome (male karyotype with testicular tissue, but female habitus and genitalia) and some instances of the adrenogenital syndrome (virilization in the female).

What one can say is that the chromosomal pattern determines the differentiation of the gonad, while the subsequent course of development—duct systems and genitalia—is hormonally controlled. More precisely the phenotypic sex (type of gonad) is the result of sex-determining genes on all the chromosomes. Male-determining genes are present strongly on the Y chromosome and probably on other chromosomes as well. Female-determining genes are probably on the X chromosome and may also exist on the autosomes. Normally the strong male determiners on the Y chromosome shift the balance in the direction of maleness. Without this chromosome female determiners tend to exert such a strong influence that the individual develops as a female.

Regarding the management of patients with doubtful sex, it is generally thought to be desirable to determine the most suitable sex as early as possible in life, considering the chromosome pattern as well as the anatomy, and, after

surgical and hormonal treatment, if necessary, to rear the child in the chosen sex.

Male Homosexuality

In the case of homosexuality earlier hypotheses implied that some male homosexuals might have a female chromosome structure. They were based on the finding of a greater proportion of males among their sibs than would be expected normally. These inferences were criticized on statistical grounds and could not be confirmed in chromatin studies on various series of male homosexuals, which showed negative sex chromatin patterns. Nevertheless, in a group of 401 consecutive admissions of males diagnosed as homosexual at the Bethlem Royal and Maudsley hospitals, these patients showed a later birth order and a high maternal age, with a variance in the latter as great as that in Down's syndrome. These data were interpreted by Slater, as supporting a hypothesis of heterogeneity in the etiology of male homosexuality, with some of them possibly connected with a chromosomal anomaly, others associated with social and psychological causes. Moreover, a number of case reports linked homosexuality, transvestitism, and pedophilia in patients with Klinefelter's syndrome. Recent reports of abnormal patterns of hormone excretion in homosexuals, if confirmed, raise questions regarding the role of endocrine imbalance as cause or effect.

Kallmann's investigation of a series of male twins with homosexuality was interpreted as suggesting a gene-controlled disarrangement between male and female psychosexual maturation patterns. Almost perfect concordance was found in a series of 40 monozygotic twin pairs, whereas in 45 dizygotic pairs the degree of concordance was no higher than that expected on the basis of Kinsey's statistics for the general population. In the explanation of these concordance data, sexual behavior was considered to be part of the personality structure rather than the gonadal or hormonal apparatus. Not ruling out the possibility that some male homosexuals, particularly the infertile ones, might have been intersexes, Kallmann generally put aside this special explanation, along with other theories of single-factor causation, in favor of a range of genetic mechanisms capable of disturbing the adaptational equilibrium between organic sex potentialities and psychosexual behavior.

It is of historical interest to quote in this connection the opinion expressed in 1931 by Goldschmidt, a pioneer in the study of intersexuality in insects:

> As far as human homosexuality is concerned, the biologist must be extremely cautious in commenting on this much disputed field. I concede that during an earlier period (1916) I was less cautious and believed, on the basis of extensive studies of the literature, that it was justifiable to

classify the clearly congenital form of homosexuality as an incipient form
of intersexuality. At present I can no longer hold to this theory. What was
discussed in the previous sections makes it very difficult to assign
homosexuals of either sex a place in the series of intersexuals. Without
pretending to be an expert in this field I should like to point out that what
has been previously said about gynecomastia (an inherited change in the
reactivity of the breast tissue to hormones) would also seem to be the
most likely explanation for homosexuality, except that instead of the
mammary gland *the brain* would be the end organ (italics added).

If the site of the divergent development in homosexuality is in the
personality and ultimately, therefore, in the "mind" or in the brain or the
nervous system, it becomes possible to study this deviation within the
framework of the function of genetics in psychiatry, tracing the processes of
interaction in the organism from its earliest origin and with its genetic
potentialities.

Some observations made by Kinsey and his associates regarding the
biological basis for the usual heterosexual choice, for example, may provoke
speculation regarding the areas of defect in homosexuality. The factors
facilitating heterosexual choice were listed as follows : (1) greater
aggressiveness in the male with a tendency to avoid sexual behavior with
another individual of the same level of aggressiveness; (2) greater ease of

intromission in heterosexual contact, with more of the "satisfactions which intromission may bring"; (3) olfactory and other anatomical and physiological characteristics differentiating the sexes; and (4) the conditioning effect of the "more frequently successful" heterosexual contacts.

In the heterosexual individual these factors would seem to require a normal rate of maturation of personality development, marked by the ability (1) to perceive and respond to biological sexual stimuli of a pleasurable nature; (2) to feel and recognize satisfaction and success; and (3) to utilize these experiences as integrating forces and guides to future action. A primary defect in perception or self-perception or response to pleasure may render an individual vulnerable to accidental or to family- or society-encouraged deviant behavior. Any vulnerability factors in homosexuality may well be of this nature, rather than what Rado calls "counter-fragments" of the opposite sex.

Other theories based on evolutionary considerations have been advanced by Hutchison and Comfort. The former suggested that the genotype responsible for homosexuality may operate on the rates and extent of the development of the neurophysiological mechanisms underlying the identification processes and other aspects of object relationship in infancy. Comfort considered the evolutionary significance of the time in which castration anxiety begins, a phenomenon that may protect immature male

animals from competitive harm between the onset of sexual maturity and the attainment of adequate size and strength. It was assumed that if this anxiety develops too strongly or too early, one reaction may be an avoidance of heterosexual behavior and a turning to homosexual behavior.

The plan used in observing those few one-egg twin pairs found with one clearly homosexual and one predominantly heterosexual partner has been referred to above. Psychoanalytic and other data on a pair of 30-year-old male twins classified as clinically discordant revealed important similarities, principally in psychological test findings. Both twins were reported as having shown marked sexual confusion and body-image distortion. Taking these results as a first approximation to the similar underlying personality characteristics expected in identical twins, the interpretation of the developmental material was focused on divergent patterns of experience. In this case, as well as in some others studied subsequently, an important factor seemed to be a difference in the twins' relationship with their mother. The preferred and ovcrprotected twin may have become frustrated in his heterosexual contacts and formed a poor masculine identification. It was assumed that the gene-influenced personality potentials were relatively vulnerable in both twins but led to homosexual symptom formation in only one. With this type of investigation aiming to pinpoint the crucial components of the developing character structure and the most sensitive periods at which they can be affected, it is obvious that many more cases must be studied

before any detailed interactional synthesis can be achieved.

Genetic Counseling

From the clinical point of view the final common pathway for the application of genetic knowledge to patients and their families is the responsible practice of genetic counseling— the provision of scientifically accurate guidance in connection with problems of marriage and parenthood. Changing attitudes and policies regarding fertility regulation, parenthood planning and population growth, and concerns with birth control, voluntary sterilization, genetic diagnosis by amniocentesis, abortion, and adoption procedures, have created an interest in and a demand for genetic information and for help in understanding that information.

The psychiatrist is involved in genetic counseling in two ways. First, he is best qualified to diagnose behavioral syndromes, as well as to interview family members and interpret records and laboratory tests. Second, he will have special skill in assessing the emotional aspects of the search for genetic information, the motivations, rationalizations, and defenses of the persons coming for help, and the impact of the information provided. Many persons accept misinformation and superstition if it is in accordance with their wishes or fears. Some couples look for reasons to avoid marriage and parenthood, while others who have had an affected child seek to alleviate their shame or

guilt. Marital problems may arise, such as hostility and sexual inhibition. Considered as a psychotherapeutic procedure, genetic counseling presents, therefore, a growing need for community mental health resources staffed by professional persons trained in modern genetic research methods, able to empathize with persons in need of guidance, and equipped with a sense of public responsibility. With proper concern the growing body of scientific and conceptual advances in genetics may be turned to human benefit, and psychiatrists may participate in the social planning that lies ahead as well as discharge their duty to foster responsible parenthood and genuinely healthy development in the families under their care.

Notes

[1] Subsequent investigations revealed that satellites are carried by all the acrocentric chromosomes, except the Y, although they cannot always be seen; therefore, the use of satellites to distinguish between acrocentric chromosomes is probably not reliable.

Chapter 6

The Personality

Joseph F. Rychlak

This chapter will be limited to the strictly psychological views of personality, as opposed to the more properly psychiatric theories. All theories must deal with certain basic philosophical questions, however, and we would like to review five such points of relevance before moving on to see how they have been answered by theorists interested in the question, "What is man?"

The Classical Philosophical Questions

What Is a Cause?

It is frequently overlooked that today's conception of a cause is only one of several used earlier in history. In particular, based upon Aristotle's theory of knowledge, one could once speak of at least four causes. The first he called the material cause. In describing a chair we can say that we know it is a chair because like most chairs it is made of wood, or metal, or the like. Another cause of the chair is the fact that it was assembled by someone or something (a machine). This Aristotle termed the efficient cause. Chairs also meet our

blueprint conceptions of what chairs "look like." This usage Aristotle termed the formal cause.

Finally Aristotle noted that there is often a purpose in events, a "that for the sake of which" something like a chair is made to come about. The "sake" for which a chair is constructed might be termed "utility" in eating, writing, and so forth. Of course, the chair docs not itself decide to "come about." It is the human being who obtained the wood (material cause) and made it (efficient cause) into a chair matching his physical requirements (formal cause) so that he might live more comfortably (final cause) who may be said to have a purpose or an intention.

Are Theoretical Meanings Bipolar or Unipolar?

When we theorize we essentially deal in meanings. The early Greeks viewed the world as consisting of "many" meanings, tying into one another by way of opposition. Just as to know "left" is to know "right," so, too, did men like Socrates and Plato assume that all meanings were at some point united through bipolar opposites. That which is "error" is tied oppositionally to that which is "truth." To split up this totality of knowledge a method termed the dialectic was employed (see Rychlak, p. 256). Aristotle eventually countered this reliance on oppositional discourse and dialectical reasoning as organon by arguing that when one begins in error he ends in error. One cannot extract

truthful conclusions from premises that are false to begin with, dialectically or otherwise. Only through premises of a "primary and true" or factual nature could science advance. This demonstrative strategy in reasoning laid emphasis on the unipolarity of meaning, in which the "law of contradiction" (A is not not-A) separated sense from nonsense.

What Is a Scientific Explanation?

Although Aristotle wanted to move the scientist out of his armchair into the world of facts, he was not above employing final causes in his description of nature. For example, in his *Physics* Aristotle theorized that leaves exist for the "purpose" of providing shade for the fruit on trees (pp. 276-277). In helping to forge modem scientific methods, Bacon later waged a spirited attack on this Aristotelian use of teleological explanation in nature. Since his time the natural scientist has made conscious effort to explain events in only material and/or efficient cause terms, with modest use of formal causality, but *no* use of the final cause.

John Locke then followed in this British empiricist tradition to say that man's basic reasoning capacities are entirely demonstrative as well, consisting of small units of unipolar meanings (simple ideas), which added up to more involved combinations of meaning (complex ideas) in quasi-mathematical fashion. Meanings thus "issued from below," and man's "tabula

rasa" intellect was passively molded via input influences from the external environment.

In Continental philosophy, on the other hand, we have the more Kantian model of intellect taking root. Kant stressed man's "categories of the understanding," which were like intellectual spectacles (formal causes) framing in meaning "from above." Whereas Locke felt that we could not—as human beings— subdivide, frame, or invent one "new" simple idea in mind, Kant recognized that through exercise of a "transcendental dialectic" in free thought man could and often did see the *opposite* implication of these Lockean inputs. This led to alternative implications for meanings were again taken as bipolar, and hence man *could* be said to influence his relationship to "reality" in a way impossible to conceive of on the Lockean model.

Are All Theories Written from the Same Meaningful Perspective?

Natural science explanation was thus to be written in material and especially efficient cause terms, utilizing a Lockean model of summative structures or, in the case of mentality, "inputs." This placed the theoretical account at a "third person" or extraspective perspective. The extraspectionist writes his theory about "that, over there," the object or organism under empirical observation. On the other hand, with the rise of psychiatry as a science of man, we see a more introspective or "first person" theory being

written. The introspectionist writes about "this, over here," the individual or subject under study in a "personal" way. In this case a more Kantian formulation is possible as we consider the intellectual spectacles as a "point of view" for the sake of which (final cause) an organism may be said to behave. This shift in theoretical perspective is probably the main alteration in scientific procedure brought about by the rise of psychiatry.

What Is Proper Evidence for Belief in a Theory?

The final aspect of knowledge that science was to affect has to do with the nature of proof. What should we require as evidence before we believe the truth value of a proposition? If one believes a theoretical account because of its intelligibility, consistency with common-sense knowledge, or its implicit self-evidence, he uses as grounds for his conviction procedural evidence. On the other hand, science was to raise the status of validating evidence. In the latter case we believe a theoretical proposition only after having submitted it to "control and prediction," which involves an observable succession of events that have been designed to test a prediction about the effect of one (predictor) variable on another (criterion) variable. Here again psychiatry has been the focal point for these interplaying vehicles for the exercise of evidence.

The Major Schools of Personality Theory in Historical Overview

One could trace personality study back to early philosophy, but "modern" personality theory is usually dated from Freud's brilliant work beginning in the closing decades of the nineteenth century. We shall formulate the major intellectual traditions in terms of Lockean versus Kantian models as reflected in man's image.

Mixed Lockean-Kantian Models and the Psychoanalytic Tradition

It is not difficult to show that Freud is a twentieth-century dialectician, who tried to find his way within the strictures of a demonstrative science that did not quite meet his theoretical needs. Freud is the father of modern personality theory because he did—seemingly unknowingly—depart from the material and efficient causes of the "medical model" to assign formal and especially final causes to man's description. His concept of a rational unconscious, directing man from out of a region of wishes and desires, was entirely Kantian in formulation. Thanks to the use of dialectic the psyche is divided into subidentities, each with its own "that for the sake of which" it operated. This is what makes Freud's account so true to life, so *human* and familiar to us who are enacting a series of daily events that we know too well are crazy quilt patterns of contradiction and inconsistency. Freud made man intelligent and introspectively directing by seeing that his physical (hysterical) symptoms were—like our chair, above—*themselves* in existence "for the sake of" causes that lay behind them (intentionality). A symptom

carried meaning, and even more complexly, such meanings were*always* compromises between two (bipolar) wishes: the repressing and the repressed!

Freud was instructed in science by Brücke and encouraged to write more scientifically by Fliess. Both of these men were uncompromising Lockeans in scientific commitment. It was under pressure from Fliess that Freud began writing his ill-fated *Project for a Scientific Psychology.* This is the clearest Lockean formulation in all of Freud, but one that he could not complete and in later years tried to have destroyed unpublished. Whereas in his very first theoretical account Freud had actually referred to antithetic ideas and counter wills (pp. 117-128), in the ill-fated *Project* he was to speak of "quantitatively determinate states of specifiable material particles" (p. 295). The former constructs are clearly on the side of formal and final causes, whereas the latter are on the side of efficient and material causes. Fliess had pushed Freud over the line to scientific respectability, but within three months' time Freud could honestly say to his friend: "I no longer understand the state of mind in which I concocted the psychology *[the Project]*" (p. 134).

What Freud *did* do in time was to introduce his libido theory, as a kind of efficient cause (thrust) and possibly material cause (does libido "exist?") translation of introspective mental mechanisms into a pseudo-Lockean frame of reference. It is for this reason that we classify the psychoanalytical

tradition as a mixed Lockean-Kantian model. Freud most surely wanted to be "scientific" in his approach, and he did *not* wish to be called a dialectician, an appellation he identified with "sophist." But anyone with the proper grasp of history can see that he made his energies behave dialectically. Drive power always issues from a dialectical ploy of some sort, oriented teleologically for goals in conflict (lust versus propriety, and so on), and then rephrased in energy terms (efficient causes) after the implications are clear.

Although he retained the essentially "reductive" tactic of Freud's Lockean substrate energies, Jung moved his concept of libido even more teleologically over to a direct parallel with Bergson's *elan vital* and Schopenhauer's concept of *Will,* both of which are teleological constructs (p. 147). Jung also clearly recognized that his therapeutic approach was dialectical in nature (p. 554). Adler was to prove the most teleological of the original founders of analytical thought, rejecting quasi-physical energies altogether in favor of an emphasis on the "natural" tendency for movement to occur in human behavior without having to be propelled (p. 41). Moreover, this movement was always fixed by some goal (telos) as embodied in a life plan, prototype, or life style (formal causes that, when exercised, permitted a "that for the sake of which" purposiveness in Adlerian thought). Let Adler retained a healthy respect for the tough-minded approach to theoretical description. His Lockeanism is reflected in a basic distrust of the idealism that our Kantian "spectacles" suggest, and Adler was adamant in his rejection of

the dialectical ploy (p. 145).

It was Sullivan more than any other person who shifted the locus of psychoanalysis to an interpersonal rather than an intrapersonal frame of reference. This was a decidedly Lockean shift, bringing about a more extraspective formulation in behavioral description. His concept of energy was far less teleological in connotation, and, indeed, Sullivanian conceptions of behavior are the most compatible of all analytical formulations with the more "mechanistic" theories of what are called in academic circles the "behavioral sciences." Sullivan relied heavily on the formal cause in his concept of the *dynamism,* or patterned energic distribution. Dynamisms were viewed as akin to the Lockean building blocks, as unipolar identities that might then combine into more complex assemblages constituting a person or a society (p. 103).

In more recent years Arieti has attempted to offset the heavy reliance of the Sullivanians on the interpsychic as opposed to the intrapsychic aspects of behavior. Whereas Sullivan had adapted Cooley and Mead's "looking-glass self" conceptions to say that man is what his environment makes him, Arieti stated flatly that "the self is not merely a passive reflection" (p. 370). Psychic identities are not *tabula rasa,* but rather the individual has a certain cognitive contribution to make to his ultimate personality. Thus we find in Arieti a return to the more balanced, mixed models of the main psychoanalytical

stream. The Kantian spectacles are now "levels" of cognitive development, moving across the age span to bring the individual to higher and higher stages of symbolic organization.

There are many other theorists who might be cited in this tradition, such as Horney, Fromm, Rank, and so forth, but we must refer the reader to the other chapters of this volume for a more thorough coverage of such views. We wish now to move into another major tradition having implications for theories of personality.

Lockean Models: The Behavioristic Tradition

Important as psychoanalysis was in the framing of man's image in the twentieth century, this theory was never popular as a formal position in the psychology departments of American academia. The difficulty lay in Freud's having to rely upon the procedural evidence of his patients. If he made an interpretation that "struck home" and aided his client's subsequent psychological adjustment, Freud naturally assumed that his theory had validity—for this client, and quite likely for all humans as well. Unfortunately, as events were to demonstrate both within and without the analytical camp, there are many such therapeutic insights to proffer, therapists to proffer them, and clients to be healed by the knowledge so garnered. If they all work equally well to heal, which "insight" is the "true" one, reflecting what is

actually taking place in the personality—a Freudian's, Jungian's, Adlerian's, or Sullivanian's?

From its very beginnings in the academic centers of Germany, psychology has sought to be a scientific discipline. Two of its important founding fathers, Helmholtz and Wundt, were dedicated Lockeans who argued that not until a behavioral phenomena had been traced back to "simple forces" (Helmholtz) and "motion" (Wundt) could it be said that a complete account of its nature was rendered (Cassirer, pp. 86, 88). We can see here the substrate efficient cause "reduction" that had been the hallmark of sound science since the days of Bacon. It remained for John B. Watson to pull together the demonstrative, extraspective, Lockean tenets of this style of "natural science" description and press them upon the study of man in his school of behaviorism. Here was a "truly scientific" rendering of human activity, one that academic psychology could embrace and further through experimentation.

As Watson said of the behaviorist: "The rule, or measuring rod, which the behaviorist puts in front of him always is: Can I describe this bit of behavior I see in terms of 'stimulus and response?" (p. 6). We recognize in this stimulus-response conception the *sine qua non* of efficient causality. As behaviorists we stand "over here" and describe the behavior of others "over there" in efficient cause terms. There is no attempt to speculate about the

"inside" of "that" person "over there." Such introspective efforts were effectively discredited by Watson. Hence teleological positions resting upon final causation are literally impossible in the behaviorist's world view. All that can transpire is an "input" (stimulus) and/or an "output" (response), each of which is extraspectively observable, hence subject to scientific manipulation. Indeed, the behaviorist typically equates his research terms (independent variable and dependent variable) with his theoretical terms (stimulus and response.) The world of reality is "out there," and the behaviorist makes no bones about his job being that of mapping it "as discovered."

What then leads to regularities in behavior? Here the behaviorists have differed over the years. Watson relied upon Pavlov's conditioned reflex and the Pavlovian-Thorndikian conception of a reinforcement that supposedly cemented this connection of stimulus and response by way of some kind of physical process. This theory has been termed a "drive reduction" view, based essentially on a belief in the efficacy of inborn needs such as hunger, thirst, sex, and so forth to establish regularities in behavior entirely outside of awareness, much less intentionality. Indeed, when he voiced his initial call for behaviorism in 1913, Watson made it clear that this approach "recognizes no dividing line between man and brute" (p. 158). This resulted in an entirely mechanical conception of human behavior, with reflexes being combined a la Lockean building blocks into habits, and congeries of habits leading to higher level behaviors at the social level (not unlike the Sullivanian conception

referred to above). But nowhere was there the dialectical clash, the internal jockeying, or the self-deceiving aspects of behavior so characteristic of psychoanalysis.

Not all behaviorists were to foster such an exclusive reliance upon extraspective theory. Tolman, for example, drew inspiration from the Gestalt theorists and proposed that animals (including man) approached life in terms of a Kantianlike *sign-gestalt* (p. 135), which acted as a sort of road may along which behavior could be directed by the individual— even in terms of his expectancies. We see here more of a mixed model and the hint of final causality, although Tolman formally rejected teleology in the best tough-minded tradition. Hull doubtless raised behaviorism and so-called learning theory to its highest level of expression, continuing in the Watsonian style of a drive reduction to account for habitual behavior. Mowrer added the significant idea that a "reduction in anxiety" could act as a potent reinforcement, leading to the stamping in of abnormal responses. Although the response is self-destructive in the long run, leading to neurotic symptoms, the fact that it reduces anxiety over the short run tends to maintain it (see Dollard and Miller section, below).

Skinner was to alter drive reduction thinking by proposing what has often been termed an "empirical law of effect" position. In his concept of operant conditioning Skinner argued that "whatever" leads to a recurrence of

the response following that response's "operation" on the environment may be termed a reinforcement. Thus, if a bear lumbering through the forest turns over a log (operant response) and is rewarded thereby with a rich lode of insects, it follows that he will be seen turning over logs on subsequent occasions. But it is not the "hunger" drive which is being reduced that leads to the later logrolling. At least, argues Skinner, it adds nothing to speculate on such "unobservable" obscurities as needs or drives "within the organism." As he once said to Evans: "I don't see any reason to postulate a need anywhere along the line. . . . As far as I'm concerned, if a baby is reinforced by the sound made by a rattle, the sound is just as useful as a reinforcer in accounting for behavior as food in the baby's mouth" (p. 10). As operant conditioning behaviorists, we look extraspectively outward and keep our theories empirically pure.

Skinner does retain the language of stimuli and responses, of course. And it is this fundamental attempt to account for all of behavior in efficient cause terms that stamps a man as a behaviorist, neobehaviorist, or whatever. In fact, the cybernetic account of behavior is comparably built on an efficient cause conceptualization. Whether we call them stimuli and responses, or inputs and outputs, whether mediations between stimuli and responses, or feedback circuits, the tie binding all such "mechanistic" accounts of man is their fundamental Lockeanism. Although Wiener has drawn parallels between man and machine, it has never properly occurred to the

cyberneticist that man has any other than a demonstrative power of reason. Yet, as Freud properly grasped, whereas the Ten Commandments fed into a machine would "teach it" or "communicate information" to it in a unidirectional (unipolar) sense, so that these proscriptions would never be violated (their premises would never be challenged), the same commands fed into a man would *of necessity* teach him "ten possible sins!" But in Skinner's world not only are all such one-sided "controls" possible, but also they are desirable and of the essence of existence. For that is the nature of behavior; it is seen as obeying determinate laws, functioning with complete efficient-cause predictability. The trick is to find how best to direct this flow of impetus factors across time.

Kantian Models: Phenomenology, Gestalt Psychology, and Existential Psychology

It was precisely the "wooden" conception of man the Helmholtzian-Wundtian and the behavioristic formulations led to that moved men like Kohler, Koffka, and Wertheimer to found a reactionary form of scientific approach they termed Gestalt psychology. This school took root about the time Watsonian behaviorism was emerging in the second decade of this century. But the Gestaltists were not the only voices rising in opposition to natural science descriptions of man. Throughout the 1920's, 1930's, and 1940's, and particularly following World War II, a rising tide of criticism was voiced by the existentialists, men whose philosophical antecedents went back

to Kierkegaard and Nietzsche. What both Gestalt psychology and existentialist psychology have in common is their conviction that traditional natural science theory applied to man somehow robs him of that spontaneous sense of subjective experience that he knows as reality. This is termed the "phenomenal" realm of experience.

It was Kant who carefully showed how reality was constituted of *phenomena* (sensory knowledge, as via seeing, hearing, and so on) and *noumena* (the presumed underlying "stuff" of "things in themselves"). Put in terms of our causes, Kant was saying that material causation was always dependent upon an assumption that "things are really there, even though all I can know about palpable events is what my senses tell me." And when we now consider the objectivities of natural science, it is obvious that they all rely on a kind of "inter- subjective agreement" between individuals who are themselves functioning within their own, private, subjective phenomenal field of awareness. Both Gestaltists and existentialists seek to say something about this phenomenal field, which, in turn, pitches their theories to the introspective perspective—making it difficult for a sensitive communication to take place with the exclusively extraspective theories of behaviorism.

There is also a kind of "hope" in the line of theoretical descent now under consideration that is yet to be realized. It concerns a new method of arriving at scientific proofs to rival the "control and prediction" tactic of

extraspective validation. Building on the theme of alienation first introduced by Hegel, and then popularized in the writings of Kierkegaard, the existentialists argue that man has been alienated from his true (phenomenal) nature by science's penchant for objective measurement, control, and stilted, nonteleological description. It was Husserl who first pointed to the need for such a variant form of scientific method. Although he worked to lay down the principle of just how this method might be conceived, the actual process was never crystallized.

Binswanger's existential analysis, or *daseinsanalyse,* is conceived in terms roughly equivalent to the phenomenological method of Husserl—as the full description of an individual's experience without "scientific" prejudice or bias, even in the sense of presuming that certain experience is normal, other abnormal, and so forth (p. 110). Hallucinations are thus phenomenally as true as are perceptions of a more "objective" cast. Through *daseinsanalyse* Binswanger essentially hopes to trace back the individual's present conceptual schemes (attitudes, beliefs, personality predilections) to what might be termed the "existential *a priori"* that conditions them, or determines their nature, much as a major premise directs the ultimate conclusions drawn in the syllogism. The Kantian emphasis here is obvious. We find the spectacles, or the "world designs" to use Binswanger's language, that frame in experience for the individual and in this way come to see *his* reality (dasein) from his subjective perspective.

What this phenomenological method has come down to again and again is 100 percent reliance upon procedural evidence. Although it may indeed be based upon intersubjectivity, and doubtless the resultant account leaves out much that is rich in a subjective sense, validating evidence does at least point to objective generalizations. With nothing else to go on, the scientist *can* state this objective "probability" as a body of knowledge without having to haggle over the details of "what do we know about phenomenon X?" And this has been the great indictment of phenomenological efforts. Not that they are wrong as to theoretical statement, but that they have lacked the methodological or evidential support to be taken as authoritative rather than simply as literary accounts. It must not be overlooked that *all* so-called clinical accounts suffer from the same problem. Freud, as we know, took psychoanalysis to be a valid scientific method, as do many analysts today. Yet not the least of the reasons that he found it so difficult settling disputes with students and colleagues can be traced to the exclusive reliance that clinical analyses must make upon procedural evidence.

Even though Gestalt psychology was to meet the strictures of validating evidence by proposing a series of remarkably creative experiments, the lock that behaviorism has on academia never really permitted this more Kantian approach to flourish. One annually hears of the complete demise of Gestalt psychology, but the truth is that it makes rather frequent rebounds under the guise of so-called cognitive psychology. The Gestaltists, too, were advocates of

phenomenology, which Koffka once essentially defined as the attempt "to look naively, without bias, at the facts of direct experience" (p. 73). Gestalt psychology is best known for its supposed attempt to prove that "the whole is greater than the sum of its parts." What has not often been made clear is that this conception of the relations between the "one" and the "many" has philosophical precedents dating back to the pre-Grecian philosophers (see Rychlak, pp. 257-267). And invariably over the course of the centuries it was the more idealistic, dialectically oriented philosopher who argued this point. Plato, for example, viewed knowledge as "one," as having "many" facets, but each of these latter aspects were configured into a single, overriding totality. By beginning at any point with a given (thesis), reasoning dialectically to its opposite (antithesis), and resolving the inner contradictions thus implied, the student (and teacher) could arrive at a higher state of totality (synopsis, later "synthesis" a la Hegel).

Although they did not press a dialectical formulation, basing their studies on sensory mechanisms such as the eye, ear, and so forth, the Gestaltists did show again and again that man contributes something to reality by way of his innate equipment (analogical to Kantian "spectacles"). Knowledge is not simply a question of information input. There are certain "laws of organization" that result in perceptual constancy, rules of memory and thought that make certain "total organizations" likely to result in one phenomenal experience while the same factors slightly reorganized result in

another. The Gestaltists were theorizing introspectively, describing what was taking place "over here," as an observer looking out onto the world studies his own processes. Their behaviorist counterparts found this sort of talk almost spiritual, harking back to the Middle Ages. There was a certain truth in this, of course, because the major factor of a "totality" is that it has organization; that is, it is a formal cause. And, assuming now that the individual may be said to behave "for the sake of" this total experience rather than simply responding to inputs, it follows that we begin taking on the meaning of a final cause in our theoretical accounts. Little wonder, therefore, that tensions were to arise. What is probably most regrettable in this academic confrontation is that the issues separating behaviorists from Gestaltists have never been made clear. Often *ad hominerm* have been substituted for rational discourse, and nowhere does one find analyses in terms of causation, theoretical perspective, or philosophical presumptions. Actually the Gestaltists would welcome such discourse, but the behaviorists find it just another example of the tenderminded theorist's mania for obfuscation and cheap verbal triumphs.

Some Examples of Classical Answers to the Classical Questions

Having now reviewed the three major intellectual traditions that have made an impact on psychological theory, we might review a number of theoretical constructs that have been proffered within these lines of descent. Since, as we noted above, the psychoanalytical tradition has been slighted in

the formal outlooks of academicians, it will be clear to the reader that psychologists have placed greatest emphasis on the behavioral and the phenomenological aspects of human behavior. It is often possible to show that these constructs were directed at some clearly philosophical issue, such as determinism versus teleology. A theorist's name and his major construct will be given in the title to each of the subsections.

Sheldon's "Morphogenotype"

William H. Sheldon has continued and furthered the style of theorizing about man that dates back through Kretschmer, Lomboroso, and others to the very founder of such speculations, the father of medicine: Hippocrates. The emphasis here is on material and efficient causation, which—-along with formal causality in the syndrome picture—has been the mainstay of all medical models of illness, including the psychiatric. Hereditary concepts are of this nature, and the transmission of various characteristics that might be seen in overt behavior is along a "chance" line, sketched entirely in terms of a Lockean model. The point here is that "genes" are "primary and true" items of physical structure that combine in various ways entirely due to physicochemical laws (efficient causes). Natural selection (Darwin) has determined the final result, for there has been no teleological advance in this descent of man. At least there has been no deity teleology or natural teleology at work. Whether there has been a human teleology— and how this is to be

conceived—is a question that has not yet been settled.

Sheldon's theory rests on the assumption that an hereditary factor termed the morphogenotype (gene-induced bodily form) is in operation. Analogizing to the in utero development of the human embryo, Sheldon argued that the morphogenotype selectively works in physicochemical terms to emphasize the development of the ectodermal (nervous system, sense organs, etc.), endodermal (visceral and digestive organs, etc.), or mesodermal (muscles, bones, blood vessels, etc.) layers of the developing organism. The resulting bodily structure at birth is predominantly ectomorphic (thin, linear, delicate), endomorphic (rotund, often corpulent), or mesomorphic (muscular, large-boned, strong). Components of each of these dimensions are to be seen in every human form, and Sheldon has devised a series of ratings to score individuals along these "primary components of physique."

Sheldon reviewed the literature on personality and devised what he termed were the "primary components of temperament," as follows: viscerotonia (people who love physical comfort, are socially outgoing, complacent, amiable, and love to eat and drink in the company of others); somatotonia (assertive, physically active people, who love risk-taking, competition, and the leader role); and cerebrotonia (people with restraint in action and emotion, a love of privacy, and a hypersensitivity to pain). Empirical study of the relationship between the physique and temperament

established that endomorphy was related to viscerotonic personality tendencies, ectomorphy to cerebrotonic traits, and mesomorphy to somatotonic behaviors. Although there are obvious problems here of the "chicken-egg" variety, not to mention the effects of diet on bodily developments, we see here one fine example of a theory of personality relying upon purely "natural science" explanation. It is not a very thorough explication of the human pattern, but neither does it presume to explain all things. Sheldon has extended his study to include individual differences among delinquents, the sexes, and so forth.

Allport's "Functional Autonomy"

One of the more challenging issues put to men who considered themselves students of personality was the question of just how behavior in the present was sustained. Addressing himself directly to the behaviorist's conception of a stimulus-response sequence (efficient cause) that had been stamped into habit by a reinforcement (material cause in physical satiation), Gordon Allport proposed that some behaviors become functionally autonomous of such "drive reductions." Although a child might have initially studied his school books because his parents showed him love and gave him financial rewards for good grades, the mature adult can in fact acquire along the way a love of knowledge per se. The "conditioning" process of earlier years is not irrelevant to the now functionally autonomous motivation, that is,

free from the tie to specific reinforcements—that the activity itself has taken on. Behaviorists would term all such "function pleasures" to be extensions of the basic drive reductions (the physical caressing from parents) as so-called secondary reinforcements (pleasure in reading, acquiring knowledge, and so forth).

But Allport was trying in his own way to break personality description free of "yesterday's" blind directedness. He rejected not only behaviorism in this regard but also psychoanalysis—where he felt that man's higher behaviors were invariably reduced to yesterday's "fixations" having no real value for the behavior as witnessed. Allport was a transitional figure in psychology, accepting the merits of stimulus-response psychology even as he tried to conceptualize human behavior in less mechanistic and hence more teleological ways. Rather than speak of behavioral habits, Allport took as his basic unit of study the construct of a trait, which he defined as: ". . . a generalized and focalized neuropsychic system (peculiar to the individual), with the capacity to render many stimuli functionally equivalent, and to initiate and guide consistent (equivalent) forms of adaptive and expressive behavior" (p. 295). Note the tie given here to the physical structure of the central nervous system (material cause). A trait is a formal cause notion, since it implies a self-bearing "style" of behavior.

Allport was thus hoping to point out that man's behavior is not blindly

habitual, responsive to stimulus input *only,* but also to some degree self-directing and stylized. Man could behave "for the sake of" an interest, a fascination, a freely operating desire that he had learned over time was worthy of perpetuating in its own right. Allport popularized Windleband's distinction between the nomothetic and idiographic sciences in psychology. Psychology, he contended, must be like history—a study of the trend line of development over the course of life. One can learn a good deal about the nature of digestion by studying the alimentary canals of thousands of animals, from lower to higher, within the confines of an isolated laboratory. But one cannot learn why the French value one style of living while the Italians another without considering the respective histories of these nations. In the same way personality as a compendium of traits must be seen uniquely evolving across time. And to immerse oneself in the first five years, as Freud had done, or to believe that only through base reinforcement does man find the motivation to approach life, as Watson had done, was for Allport a common error in theoretical formulation. Man can be functionally autonomous from such base reinforcements, as he can be functionally autonomous from the fixations of toilet training.

Murphy's "Canalization"

Another historically important attempt to counter the more "mechanical" formulations of stimulus-response psychology was made by

Gardner Murphy, when he distinguished between conditioning and canalization—a term used earlier by Pierre Janet in a different sense. A conditioned response, said Murphy, was indeed a mechanical sequence of events (efficient causes). But these movements were simply preparatory; they oriented the animal for eventual gratification that was itself more in the nature of an anticipated achievement leading to goal realization (p. 193). As the restaurant waitress approaches our table to take our order, there are various mechanical, unthinking conditioned responses that we make in ordering our meal; for example, we arrange our plate and table utensils, tap nervously on the menu, and so forth. But the consummatory act, the *goal* of eating what we choose to eat, is not itself a conditioned response or a class of such responses. What a person comes to prefer, comes to work for and select in life is not simply conditioned—it is canalized. Behavioral patterns thus become fixed through active, purposive, self-directed attempts on the part of the individual to channel (canalize) his behavior in terms of something he has personally discovered to be satisfying. Conditioned responses are passive and routine. Canalizations are active and selective.

Thus man is passively shaped in the Watsonian sense, but he is also actively self-created through a process of anticipation and achievement (p. 170). One can see here an effort to bring some modicum of "that for the sake of which" into personality theory. As Allport would have it, man passes through life with an intellect open to the possibility in things. He is being

demonstratively "input" with experience, but he has this capacity to evaluate such input, to take delight as well as to respond with simple animal satisfaction. At some point the taking delight begins selectively to direct what is satisfying. This directing or canalizing is entirely on the side of a final cause, possibly also including the formal cause as a kind of plan, wishful design, and so forth. Murphy thus did not deny the behavioral findings of the rat laboratory. He simply wished to point out that there was more to human behavior than this routine, blindly repetitive series of responses. Choice and purpose were "in" the picture.

Murray's "Regnancy of a Need"

H. A. Murray was to solve the problem of directed behavior in somewhat more physical terms than either Allport or Murphy. The behaviorists had referred to needs as specific tissue deprivations of some sort, as in the case of hunger or thirst. Murray was to broaden the scope of this term, using it much as Allport had used traits to include the purely psychological aspects of behavior. He viewed the need as a hypothetical property of force, presumably a force in the brain region that organizes behavior in a directional sense (p. 123). Needs generate action, which, in turn, eventuates in some counteracting environmental force termed a *press.* The individual with a great need for achievement might well find that there are forces in his experience that counter an easy access to wealth, the attainment of accolades for athletic

prowess, or the professional recognition from colleagues. There are all kinds of environmental pressures against which the individual must struggle in order to gain the satisfaction of his needs.

The typical fashion in which people go about meeting their needs in the face of counteracting pressures from their life's milieu Murray called the *thema.* This entire theoretical account is essentially an analogy from Murray's projective test, the Thematic Apperception Test (TAT). In the same way that the clinician analyzes a "hero" figure in a TAT story, so, too, does the personality theorist assess the individual in his life circumstance.

Murray proposed a series of need terms to be used in the description of behavior, including aggression, achievement, affiliation, exhibition, order, and so forth. Precisely what an individual is like in personality could now be assessed in terms of the particular combinations of his unique needs, their level of satiation or deprivation, and the life circumstances (press) that faced him. The highly affiliative person, for example, after a period of time in which he might be forced to be alone, could well begin appearing highly frustrated and even abnormal simply because of his rising need state and the circumstances of his life milieu. Murray retained a physical tie-in to the functioning of the body, making an effort to resolve the dualisms of Freudian or Jungian formulations. Dualisms have never fared well in psychological academic circles. The behaviorists had argued that habits took on a

hierarchical arrangement—from lower-level, simple stimulus-response connections, to higher-level complexities of a more global nature (we see here a Lockean model being pressed). Murray now builds on this conception by arguing that certain needs were prepotent (overriding force) to other needs. Such needs demand answering in the "now"; they dominate our brain process as *regnancies*(predominant physiological reactions), assuring that some form of behavior will be undertaken to seek the goal that can satisfy the condition of a rising motivation (p. 45).

Since the need concept is now a psychological one, we can say that Murray has effectively resolved the dualism of classical analysis by claiming "wishes" or "cathexes" are regnant brain processes. The man under regnant brain processes heralding a prepotent need for achievement is to be seen driving himself forward across life's way to success at all costs. This theoretical usage puts a kind of directionality (final cause) in the account without actually making it seem that way, because all needs are either given at birth in physical constitution or they are "learned" (input influences a la Lockean model) over the years of development. Hence the image of man here is more introspective than classical behaviorism would have it, but we still do not find that heavy aura of the "internal world" that Freud and Jung provide us with. Murray has milked the dialectical side of man out of his theory. Man no longer takes in an input meaning, reasons to its opposite meaning-implication, and thence directs himself via a true choice to some alternative

or compromise creation all his own. Man is directed by regnancies emanating from physicochemical forces in the brain, forces that have been planted there by nature or by the social milieu. What quasi- dialectical clash there is takes place between these internal forces (needs) and the external counterforces in the milieu (press). But man *qua* man is not "in the middle" as Freud believed him to be, with an ego identity struggling internally to compromise the wishes of the id and superego identities.

Dollard and Miller's "Anxiety''

An even more thorough job of taking the dialectical capacities of man out of his theoretical conceptualization was accomplished by Dollard and Miller. Their motives were laudable, in that they hoped to cement laboratory theory of a Hullian cast with the insights of the consulting room and thereby unite psychology in a way it had never been united previously. Since stimulus-response theory is more abstract than clinical formulations, this translation could have been performed on Adler, Jung, Sullivan, and so forth. But Freud was selected, and the procedure adopted was to rewrite Freudian terminology into the more abstract Hullian terminology of cue, drive, response, reinforcement, habit, and so forth. This is a drive reduction theory. A "drive" is a strong stimulus impelling action, which, when reduced (material cause), acts as a reinforcement of the stimulus-response regularity (efficient cause) that preceded it. Freud's sexual concept is interpreted as such a drive.

There are basic drives (such as pain) and drives of a secondary cast, which can be easily attached (learned) to stimuli that do not ordinarily bring about a basic drive arousal.

One such secondary drive is anxiety, which is interpreted as a learned drive having the properties of fear, except that in the case of anxiety the source of the threat is vague (p. 63). We fear a train bearing down on us, but we are anxious knowing why. The point of importance for learning theory, however, is that when such vaguely stimulated anxieties are reduced—when we flee the elevator situation (claustrophobia)—this return to a normal emotional level acts as a reinforcement. It samps in the flight response, in relation to the elevator stimulus. Hence the next time we face an elevator situation we will be sure to flee in order to reduce the anxiety that has once again mounted due to inexplicable reasons.

Now this theoretical treatment of anxiety has become extremely important in psychology. For example, it lies at the heart of the so-called behavioral approaches to psychotherapy (see, for example, Wolpe). It has proved very popular because, just like Murray's regnancies, we have reduced the Freudian dualisms of mental events versus bodily drives to a single, hence monistic, formulation. This is all very much in the traditions of natural science, and the essence of this tactic is to say that a physically based drive (material cause) brings about and sustains behavior (efficient cause) entirely

"on its own." The neurotic's symptom is sustained because he reduces anxiety by performing it. His grasp of why he does this is vague, thanks in part to the fact that he has not paid sufficient attention to his life circumstances in the past. For example, when he was frightened as a child in an elevator, he "stopped thinking" as a response ("repression") and therefore never really knew what it was about the elevator that actually set off his fear (a loud noise, a frightening passenger, the fact that he was being taken to the dentist, and so forth). So far as learning theory is concerned, the actual reason for the symptom is unimportant, or at least quite secondary to the fact that a symptom now is coming about and must be removed.

Although many psychoanalysts today would agree with the statement "neurotics behave as they do to avoid anxiety," the actual translation of an introspective, Kantian-Lockean (Freudian) model into an extraspective, entirely Lockean (behaviorism) model *has* lost something in the translation. In the first place Freud's concept of repression was not one of a passive "stopping thought," or overlooking possible cues in the environment. The unconscious mind, according to Freud, knew only too well what it feared or lusted or hated. Second, Freud definitely did not want anxiety to take over the motivation properties of the personality structure. That was the job of libido —an entirely mental construction of force or drive. This is why he stressed that only the ego could experience anxiety! As is well known, Freud relegated anxiety to an instrumental role as a warning sign (pp. 57-59). The warning to

consciousness in neurotic anxiety was something to the effect: "watch out, your lustful desire for mother and your wish to kill father is going to pop up here in a moment and then you will have consciously to admit that you are a rapacious, incestuous pig and murderer." The conscious aspect of the ego is "inoculated" with a modicum of anxiety so that, rather than consciously dealing with such incestuous and murderous intentions or "wishes" (final causes), it deals with an unpleasant physical sensation (material and efficient causes). But to say that symptoms are aimed at avoiding anxiety is completely to misconstrue the meanings of Freudian theory. Neurotics behave as they do not to avoid anxiety, but to avoid the awareness of their completely psychic, unacceptable intentions!

Hence the wedding of Freudian and behavioral theory must and has altered the image of man being described. Theorists are dualists (mind-body) for reasons, and when one alters the necessary teleological implications of this dualism to meet the strictures of monistic scientific thought, he violates the reason impelling dualistic formulations from the outset. Freud had his Fliess, his "natural science conscience," and he gave the Lockean model a sincere effort in the *Project.* But he could not forego the meanings he was trying to convey by conforming exclusively to the style of description that Dollard and Miller were later to employ. Hence we must count the latter's laudable efforts as only partially successful, through no real fault of their own. Some meanings simply *must* stand as framed.

Cattell's "Source Traits"

Baymond B. Cattell must surely be the foremost theorist to take a measurement approach to the assessment of personality. There is much of the Allport and Murray tactic in Cattell, for he begins with the assumption that behavior is constituted of traits, and that these Lockean building blocks combine to form the personality superstructure. Bather than a hierarchy Cattell speaks of a "dynamic lattice" in which some traits "subsidiate" (take precedence over and hence enter into) others. The unique twist that Cattell gives to the Lockean model is that he sees both surface and source traits in behavioral operation. Surface personality traits are the apparent manifestation of individual differences, superficial assessments that we make as observers because we have no way of directly viewing the commonalities lying beneath. Source traits, on the other hand, "promise to be the real structural influences underlying personality" (p. 27). Thus by using the trait designation Cattell captures a formal cause meaning, but his "source" adaptation gives us a kind of analogy to the reductive explanations of natural science. We get a quasi-material and quasi-efficient cause meaning here through rough analogy, if nothing else.

What one must do to jump the gap between a surface and a source trait manifestation is carefully to measure overt behavior and then submit these crude empirical measures to the statistical refinement of factor analysis. One

finds in this way a common "factor" accounting for various overt manifestations. In time a series of reference factors having universal relevance to behaviors will be empirically identified and carefully validated. This collection of source traits (universal index) can then be applied by the psychologist much as the chemist makes use of his periodic table of elements. So much of source factor A, combined with so much of source factors B and C, results in what we call superficially the (surface) trait of "leadership," and so on. Although an oversimplification this portrayal of Cattell's approach is basically accurate, and we can see in it the substrate notions of Lockean "simple" structures combining to form the higher order, "complex" structures. The specifics of just how personalities got to be the way they are "now" constituted would depend upon the typical "input" notion (efficient cause) of environmental influence, including conditioning and hereditary explanations.

Skinner s "Contingency"

We have already noted above that B. F. Skinner was an important figure in the "empirical law of effect" interpretation of reinforcement. Rather than attributing behavioral regularities to such "inside the organism" concepts as needs, wishes, aspirations, intentions, and so on, Skinner argued that only those responses that "operate" on the environment to bring about rewarding events are retained by an organism. At least, most of an animal's response and virtually all of human responding is of this nature. Skinner termed this an

operant response, and that "something" in the environment that serves as a reinforcement of such operants he termed a contingency. What are the contingencies of reinforcement available to an organism in the environment? If we know this, then we can easily predict what behavior it will *emit,* for behavior is always under the control of some class of empirically demonstrable reinforcing contingencies.

Although Skinner is not precisely a "personality theorist," surely his image of man has been given enough serious consideration by specialists in this area to rank him at the very top of contributors to the study of personality. And what he constantly emphasizes in all of his characterizations of man's behavior is that the environment and not man is the selective agent in behavioral control. He specifically rejects the concept of "autonomous man" (p. 67). Skinner, more than any other modern psychologist, is an uncompromising classicist in his image of man as exclusively an efficiently caused succession of events. He has acknowledged a debt to British empiricism (Lockean model) by noting to Evans that he "short- circuited" Kantian formulations (p. 15).

An even more remarkable observation on his theoretical stance is reflected in the following: "Operant behavior, as I see it, is simply a study of what used to be dealt with by the concept of purpose. The purpose of an act is the consequences it is going to have" (Evans, p. 19). We find here an almost

startling preempting of the final by the efficient cause meaning. Through viewing man exclusively on extraspective terms, and fixing on the consequences of "that" behavior "over there," Skinner can assess the consequences (contingent reinforcements) of "that" behavior to see which consequences perpetuate it and which do not. Once he determines empirically what such contingencies entail, he can exert what he takes to be a form of efficient cause control over it. But what if the organism "over there" is considered introspectively and judged to behave "for the sake of" personally held intentions, after all? What if, in the case of man, rather than his being under the control of the extraspective manipulator, he is actually simply conforming or cooperating with what he takes to be the manipulator's purposes?

Well this would make no essential difference to the Skinnerian formulation. For example, psychologists have shown to general satisfaction that "being aware" of the response- reinforcement contingency, or, in other terms, knowing that verbal behavior X will lead to reinforcement Y, decidedly facilitates the efficiency of learning verbal behavior X. Some psychologists claim that there is very little, if any, verbal learning without such an awareness on the part of the subject. This could easily be taken as evidence in support of a final cause view of behavior, with the response- reinforcement contingency interpreted as "that advantage, clue, goal, or plan for the sake of which" behavior is acquired and perpetuated. Yet such questions are not

thought worthy of serious theoretical consideration in the Skinnerian world view because what is fixed upon is *only* the flow (impetus, efficient cause) of events across time. This is taken as "behavior." Just so long as it can be shown that certain contingencies lead to behavioral pattern A and other contingencies lead to behavior pattern B, this is all the Skinnerian feels obliged to deal with as he perfects his ability to "control" such patterns—from A to B and back again.

Rotter's "Expectancy"

When Tolman was working out his variant brand of "purposive behaviorism," he emphasized that input stimuli are rarely translated directly into output responses, because as Woodworth had observed, there is a certain "mediation" of the organism in between. This Kantian notion of a "cognitive map" was central to the Gestaltist theorists who inspired Tolman, but in accounting for the continuing influence that an organism (rat, man) has upon his experience, Tolman was to speak of what have ever since been called "mediators" in learning theories. Dollard and Miller have made considerable use of this mediation construct in their translations of Freud. Higher mental processes (thoughts, words, language) all come down to an operation of some such mediating "cue stimulus" or "anticipatory goal response." Animals learn to begin responding even before they see their reward (reinforcement), said Hull. Anthropomorphizing, we might say that the dog "knows" his dinner is

waiting ahead, for he salivates noticeably and breaks into a more rapid run as he sees his master's house ahead. But actually the dog anticipates nothing at all. He has simply been trained to respond to certain "antedating" cues, so that over time his salivation response began moving ahead in time, from his food dish, to the door leading from outdoors, to the silhouette of the entire house ahead, and so forth.

Hull was the behaviorist to develop this line of theory most creatively, and he was obviously trying to account for what in other contexts might be termed intentional or purposive behavior without resorting to a teleology. In personality study Adler and Lewin had been developing conceptions of human behavior based on what has since been called the level of aspiration. Adler made no bones about this being a teleological conception, claiming that people laid down a definite plan (prototype, fife plan) "for the sake of which" they then aspired to further their advantages in living. Lewin's conception was also teleological, but he was not quite so outspoken because he was trying to meet some of the natural science objections to final cause description.

It remained for Julian B. Rotter, a theorist who was influenced by Hull, Adler, and (to a lesser extent) Lewin, to raise this conception of aspiration level to what is probably its most thorough and well-rounded expression. Rotter changed the descriptive label to expectancy, but it has the same

meaning of "that for the sake of which" an individual may be influencing his behavior. The child who expects to earn (aspires to) school grades at the A level is crushed with a grade of B, whereas the child expecting C's is elated with the same achievement. One's life circumstance cannot be entirely circumscribed by the "simple facts" of reality. Rotter also added the concept of reinforcement value to say, for example, that even some things that are easy to attain in life are not valued. If we wish to predict behavior we must know not only what the person is expecting, but how much he values that which is upcoming. The child who docs not value education will give little effort to it even if achieving good grades is relatively easy for him.

Although he has moved his descriptions over to the introspective perspective, and his account is far less mechanistic than the classical behaviorist's, Rotter's psychology remains heavily Lockean in tone. He is clearly in the line of descent we have been reviewing to this point. Expectancies amount to past "inputs," learned through conditioning in experience on the basis of an empirical law of effect and functioning in the present as special kinds of mediators. The value of reinforcement is also a function of past reinforcement. Man is not viewed as capable of reasoning to the opposite of what is given, drawing out an expectancy- aspiration of some other possibility, and then aspiring to what was *never* known, much less reinforced, in the past. Yet Rotter's theory is probably best classified as a mixed Kantian- Lockean model, and he forms a nice bridge to the more clearly

Kantian approaches we now turn to.

Lewin s "Life Space"

Although he was not an orthodox Gestalt theorist, there can be little doubt that Kurt Lewin received considerable stimulation from the work of Wertheimer, Koffka, and particularly Kohler—all of whom were his colleagues for a time at Berlin University before he came to America. Lewin took the Gestalt concept of a perceptual phenomenal field and drew it out into a view of the life space, or the total psychological environment that each of us experiences subjectively. This (formal cause) construct embraced needs, goals, unconscious influences, memories, and literally anything else that might have an influence on one's behavior. Rather than seeing behavior as an incoming process of stimulus-to-response, Lewin constantly stressed that behavior takes on field properties as an ongoing process of organization and interpretation following Gestaltlike principles.

The course of behavior follows paths or pathways between one's present location in his life space and the goal or goal region (level of aspiration) that attracted him. Other goal regions might repel the individual (negative valence), and it is the sum total of all the field forces (efficient causes) entering into an overall pattern (Gestalt, formal cause) that led to behavior (locomotion) within the life space. Hence behavior was directed, and

although Lewin might be said to have introduced a modicum of teleology in this more introspective account, the directedness of this behavior was put extraindividually in the sense that the "person" or "personality" is merely one organized subportion of the entire life space. Motions within the field (efficient causes) can be induced by any portion of this life space.

Lewin's handling of teleology is therefore quite unique and rather moderate in relation to the more extreme final cause formulations that can be tied to man's image. The life space is, of course, a derivative concept of the Kantian categories or predicating "spectacles" that are the major contributor to behavior in this theoretical style. But Lewinian psychology is not a complete idealism. Lewin accepted what might be termed a noumenal world on the "other side" of the phenomenal life space. Such influences on behavior as the fact that a path under our foot is slippery, or a roof over our head leaks water, were influences emanating from the foreign hull. As a permeable membrane the life space (formal cause) interacted with such foreign hull influences (material causes), making such alterations in its organization as were called for and mutually altering the status of the foreign hull by reciprocal influences.

Kelly's "Personal Constructs"

One of the most clearly Kantian formulations in the literature is to be

seen in George A. Kelly's "Psychology of Personal Constructs." Unlike Rotter, who viewed expectancies as past input influences based upon a reinforcement principle, Kelly ascribed an active intellect to man, one that construed experience rather than passively took it in. For Kelly an expectancy is to be thought of in terms of both a formal and a final cause meaning. It is a stylized meaning through which or "for the sake of which" the individual advances on life daily. Of course, Kelly's actual term is that of the personal construct rather than the expectancy. Just as Kant had argued that freely created thought is dialectical in its essence, so, too, did Kelly view the process of construing as bipolar in nature (p. 304). When one affirms the commonality of events that he has observed recurring over time, he must also negate some other aspect of that recurring experience. To say "Redheads tend to be hotheads" is also to say "Nonredheads tend to be level-headed."

Thought is only possible, said Kelly, because man can dichotomize elements of experience into similarities and contrasts (p. 62). The products of thought, or constructs, state in either clear or highly nebulous terms how "two elements are similar and contrast with a third" (p. 61). Constructs are working hypotheses, predictions, appraisals, and even pathways of movement, for they frame in our meaningful experience like transparent templets (Kantian spectacles), and hence predetermine just what is possible for us to do. Man is determined mechanically only when he construes himself in this fashion. Constructs are either permeable and capable of change, or

they are impermeable, rigid, and frozen into a form of thought Kelly termed pre-emptive. To change behavior we must change the constructs determining that behavior. The philosophy that expresses a strong faith in man's capacity to do precisely this Kelly termed "constructive alternativism." Although constructs are ultimately highly subjective or "personal" in nature, they can be understood introspectively if we make serious efforts to see things from the slant of the personality under study.

Constructs can also be objective in that many men can understand the meanings implied in the same set of constructs. To further a clinician's ability to identify the constructs of his clients Kelly formulated the "Role Construct Repertory Test," or, more simply, the "Rep Test." A role construct is one that defines the individual's more important interpersonal behavior; for example, when he perceives another individual as also a construer, and to that extent enters into an interpersonal relationship with him. By contrasting and comparing how various figures in his life (mother, father, best friend, admired teacher, disliked associate, and so forth) were like and yet different from a third figure, Kelly was able to fashion a list of core personal constructs that he then used to see the world from his client's eyes. "How are your mother and ex-girlfriend alike, and yet different from your wife?" This would be a typical example of the way in which role constructs are evoked. The individual is free to select his own terms. Kelly devised a nonparametric procedure for factor analyzing these many different constructs to find the very heart of the

individual's construct system. This idiographic manner of factor analyzing data is quite different from that of Cattell's, and the image of man that results is, of course, diametrically opposed to the Lockean formulations of the more nomothetic approach.

Maslow's "Third Force Psychology"

Abraham Maslow coined the phrase "The Third Force" in psychological theory by which he meant an approach in the traditions of people like Allport and Rogers. He seems to have identified this approach as "humanistic psychology," a phrase that has achieved considerable prominence in the post-World War II era. After passing through a period of fascination with Watsonian behaviorism, Maslow moved on to emphasize such concepts as self-actualization, human potential, and peak experience. These terms attest to man's capacity for teleological advance, based upon a hierarchy of lower-to-higher needs that rest upon one another, yet are fundamentally independent of each other. Maslow thus picks up the conception of need developed by Murray, as dealing with both physical and psychological necessities. Physiological needs lie at the base of the hierarchy of needs, with higher-level needs such as love, esteem, the need to grow and self-actualize coming into the organization as kind of emergents. The important point is that one cannot find the meaning of higher-level needs by reducing them to the lower-level needs. Further, it is inevitable that as the lower-level, physical

needs are being met, the more humanistic needs will begin to seek expression and gain satisfaction.

Hence, just as neo-Darwinian theorists speak of emergents in the evolutionary processes of nature, so, too, does Maslow rely upon this tactic to modify the Lockean hierarchy that held that the lower levels constitute higher levels and to know the latter we must deal with the formed. This is a clear Gestalt or holistic infusion, a tempering of the more mechanistic features of Lockean thought while striving to retain continuity with the physical aspects of nature. As a theoretical device it is comparable to Freud's uniting of body (physical) and mind (psychological) through use of the instinct concept. Maslow actually based much of his thought on biological conceptions, feeling that there was a "growing tip" to the advance of organismic life (natural teleology). If we want to get a sense of the higher life that evolution is making possible, we should investigate our more self-actualized human life histories. Maslow did just that, isolating the factors of important historical figures like Lincoln and Einstein, whom he judged to be self-actualized individuals.

Maslow claimed that self-actualized individuals see life more clearly than other people. They are more decisive and can take a stand with greater confidence, for they are prepared to name what is right and what is wrong about life. They have a childlike simplicity and usually admit their lack of knowledge in an area of what is clearly their expertise. Though very confident

they are humble and more open in their general approach to others. Without exception they have some worthy task to which they commit themselves completely—a career, duty, or vocation that presses on them, fascinates them, and gives them a sense of fulfillment even though it is not always easy or pleasurable to accomplish. They are, above all, spontaneous and creative in their behavior, willing to "be themselves" for they lack pretense and defensiveness. Mas- low coined the term *Eupsychian* to describe the society that a group of such self-actualized individuals would form if left to their own devices—say, on a secluded island. Presumably the society would reflect their common tendencies: a biological utopia of our very best, the "growing tip" dipped off and transplanted to flower as all utopias do—apart and unmolested by the common foliage.

Piaget's "Schemata"

Although he worked for years in relative obscurity, Jean Piaget has assumed major importance in the outlook of many psychologists during the post-World War II years. Piaget has a concept of the schema that is reminiscent of Kellyian constructs, but it takes on a developmental frame of reference in that presumably we are dealing here with innately prompted constructions. Thus Piaget argues that schemata are first brought into play on the basis of reflexive activity, as when the infant first employs his sucking reflex, bringing it to bear on the mother's nipple. This process of aligning a

patterned behavior (schema) to a proper stimulus Piaget termed accommodation. Once fixed in this fashion the experience of sucking takes on meaning to the child, although of course, the extent of meaningful grasp is limited due to the lack of language. One sees here a decidedly introspective formulation of what is a formal cause term (schema, pattern). The nature of human maturation is now a question of extending and in time patterning various schemata into more and more meaning. The child begins to notice and suck other objects—his fingers, a blanket, and so forth—coming to enlarge this already accommodated schema. This process of enlarging and enriching schemata Piaget termed assimilation.

The essence of Piagetian motivation theory is that the child and then the adult tries to keep his schema relevant and applicable to experience. Schemata that are not assimilable are meaningless by definition, so it is essential to human intelligence that a continuing growth takes place. Much of Piaget's empirical work has involved the study of maturing children, tracing how this process of continuing, expanding, and changing schemata takes place. For example, he early found that the natural experience of reality for the child is anthropomorphic. The child perceives natural events of all sorts, including rain, wind, and so on in terms of intentions and willful acts. The five year old says that the sun's rays push the wind into activity or organize the clouds to look pretty. Only by about age eight or ten does the child completely divest the physical world of human qualities and view it in purely physical,

mechanical terms. Piaget called this early phase "precausal" thinking, but we can see here the time-honored issue of final-formal versus material-efficient causes manifesting itself. The basic question is: do children think "primitively" or do they think entirely "naturally," so that their teleological formulations are actually the phenomenal truth? Piaget leans in the former direction, and thus he departs from existentialism.

Rogers' "Wisdom of Organic Evidence"

It is well and good for science to lay down its principles of explanation, viewing animistic explanations such as children proffer to be "precausal" or "primitive," but does this change what is taking place? The child does, after all, experience intentionality phenomenally. Who is to say that this experience is not therefore just as vital to the meaning of existence as the so-called scientific laws that presumably are the "real cause" of such experience? Although anthropomorphic experience may be recast in the efficient cause substrate of stimulus-response psychology, this does not mean that the causes that propel the individual through his phenomenal field are being identified. What if teleological considerations are at play? This line of argument takes us deeply into the phenomenological-existentialistic or "cognitive" theoretical sphere, and a foremost spokesman here has been Carl R. Rogers.

Rogers is widely known for his expounding of a phenomenal field construct, which is similar to, although more subjective than, Lewin's life space concept (p. 97). Man's physiological-biological and psychological experience combines to funnel into his organismic experience by way of the phenomenal world. Distinctions of body-mind are thus dropped for all practical purposes since, in essence, man comes to know as much by way of his sensory feelings as he does by way of his conscious symbols. Indeed, says Rogers, there is "a discriminating evaluative physiological organismic response to experience, which may precede the conscious perception of such experience" (p. 507). This organic valuing process is important to the individual. It has a sense of what is worthy and true phenomenally even before rational justification might be given symbolically in words. Hence there is in a sense wisdom within the organic evidence of feeling tones. Extending this, Rogers literally comes to a "naturalistic ethic," for he claims that people all over the world have a common base of organismic valuing, stemming essentially from man's common base in organic evolution. As he summarizes it: "The suggestion is that though modern man no longer trusts religion or science or philosophy nor any system of beliefs to *give* him values, he may find an organismic valuing base within himself which, if he can learn again to be in touch with it, will prove to be an organized, adaptive, and social approach to the perplexing value issues which face all of us" (p. 441).

Hence modern man must be unafraid to be "what he is." He cannot allow

science to define him or to control him. To be what Rogers calls the fully functioning person (Maslow's selfactualized individual), the human being must trust to his feelings and to the feelings of others. Science may tell the person that he is under the control of outwardly determined natural laws, but what does he subjectively perceive (phenomenally) if not a sense of personal decision and self-direction? Rogers moved from individual therapy to a concern with group encounter based on this naturalistic ethic. The point of sensitivity training is to make one aware of his personal contributions to the phenomenal reality of others. By turning in on himself and discovering a pattern of natural feelings very similar to others, the individual can drop the facades of social niceties and the masks of social defenses. The person as enacted in overt behavior can become "one" or congruent with the feeling tones he has been ignoring or denying in the past. With everyone in the group 100 percent in tune with their sincere feelings, a higher level of phenomenal living is achieved.

In one sense Rogers has avoided the dualism of mind-body in his uniting phenomenal field construct; but in another he has brought on a second dualism of the "feeling versus symbolizing" variety. Although clearly a Kantian and having the typical existentialistic-phenomenologistic approach to man, Rogers comes back to a firm basis for ethics in the physical reactions of the body. Material causes (feelings) somehow clue us to what is "best" (final cause) through a patterning of sensations (formal cause). They tell us when

we feel this way or that, and no further "reason" —reduction to substrate stimulus-responses, or Freudian fixations—is needed for a more healthy pattern to emerge. If everyone listened to their feelings and behaved genuinely, in time behaviors would seek their level. The bully would acknowledge his hostility and the coward would express his fears in a way never before possible. The result would be a more genuine, sincere, fully functioning life for all.

Boss's "Meaning Disclosing" Dasein

In developing our phenomenological tradition we have made it appear that all theorists in this line are clearly Kantian, that they take on some such "spectacles" notions as Binswanger's world designs, Kelly's constructs, or Piaget's schemata. Actually there are positions that are not this easy to classify within the phenomenological camp. Medard Boss is an excellent case in point. Although both he and Binswanger were stimulated by the philosophy of Heidegger, Boss's interpretation of the latter's philosophy seems closer to accuracy. Heidegger—at least in his later writings—was trying to avoid the separation of Dasein (existence, experience) into the *a priori* (Kantian spectacles) and the *a posteriori* (the resultant existence as phenomenally gleaned). The meanings of Dasein for Binswanger and other classical Kantian views are "endowed" by the world designs that frame in experience. For Boss, on the other hand, Dasein is always "disclosed." Boss

liked to speak of it as *luminating* or shining forth, disclosing itself to man's awareness rather than vice versa (p. 39).

This has the practical effect of making Boss's existentialism appear more Lockean in the sense that Dasein is issuing toward awareness in a quasi-input sense. Actually, of course, this is not the intent of Boss's construction. What he is emphasizing here is the completely free and unbiased nature of phenomenal experience. Even a Kantian "category of understanding" is to that extent forming experience. It is pressing on experience something that is not part and parcel of that experience, much in the way that science presses its arbitrary efficient causes onto teleological behavior or Freud presses his infant analogues onto mature behavior. We must not reduce one level to another in a truly phenomenological-existential approach.

This "purity criticism" can be taken back in the history of modern existentialism to Kierkegaard's ridicule of Hegelian logic (see Rychylak, p. 390). Hegel had concocted a logic that was a brilliant example of how the mind can create "a position." But when Hegel now took this to be "the" position he made himself ridiculous on the fact of things, said Kierkegaard. In like fashion the very heart of existentialistic positions has always been to undermine the pat, the set, the rigid certainties of contrived experiences. What it seeks is "pure" experience, as immediately luminated to the mind's

eye. The anthropomorphizing child is therefore not "primitive"; he is entirely "human" (see Piaget, above). Man is teleological in his essence, and he must therefore take responsibility for what he does. Existentialists catchwords like commitment, engagement, and confrontation flow from this philosophical premise.

The Final Question: What Is Personality?

It should be clear now that the reason it was impossible to write this chapter around "the" personality is because of the interlacing classical issues framed by our opening questions. It does seem that a personality term borrows greatest meaning from the pattern or style of behavior witnessed among people. This would make it predominantly a "formal cause" term. Such styles are usually first identified in terms of the "total" person, so that the personality scheme is likely to begin as a typology. We study individuals and construe an oral or anal personality picture. Then, as surely as anything, the type gradually develops into a trait theory as we begin seeing signs of orality and anality in other and then all people "more or less." This is not to say that trait theories cannot begin as such; it is to suggest that the usual historical pattern has been to move from typologies to trait theories.

It is when we begin to explicate why there are such "individual differences" among people that our other causes come into play. A classical

solution here is to fall back on genetic-hereditary explanations, as in the morphogenotype of Sheldon. There is almost no rebuttal to this proclamation that people differ because they are born that way. Enlarging upon this we can say that people differ because they have different needs, or that their needs (instincts, drives, etc.) have been differentially met. We can now extend this to in- elude learned needs, and even Rotterian expectancies that serve to influence behavior in one direction rather than another. The behavioral approach of stimulus-response psychology has been fundamentally opposed to the study of individual differences in behavior. Individual differences are merely differential controls being exerted on the basic organism that itself follows common (basic) laws. Needs are reinforcers when met, and insofar as the term "personality" has any meaning at all, it refers to the habit hierarchy that results when these reinforced behaviors have been fashioned or "shaped" (formal cause) by experience.

The social milieu is extremely important to the behaviorist's formulations, since it must be assumed that the inputs that fashion behavior are prompted by one's culture, social group, and so forth. In the final analysis every behaviorist psychologist is a social psychologist. Cattell's test-based conceptions of personality are no different, for he would think of personality as a set of source characteristics employed by a psychologist to predict how person X behaves in situation Y. This is a fairly general attitude among laboratory psychologists, who have moved away from the more classical

personality grand theory formulations to rely increasingly on measurement and methodological test to substantiate a more restricted area of study, which is sometimes called a miniature theory. But the upshot is that individual differences and uniqueness in the study of personality have given ground to the more common formulations of behavior. This "common" behavior is well-captured in efficient cause terms, such as the S-R construct. But what of the style of such behaviors? And how much influence docs the individual himself have on this styling of his personal behavior?

Those theorists who reject the more passive, Lockean conceptions of the human condition argue that behavior is also shaped by the individual, who formulates personal constructs (Kelly) or furthers schemata (Piaget) over his lifetime. Man is a potentially higher animal for some (Maslow), and hence we can not find his unique humanity in the reductive common substrate of a lower form of behavior. The phenomenologists and existentialists take this a good deal further, and staunchly defend the thesis that only man can be the measure for man.

When we now focus on that most human of all animals we must of necessity ponder the corollary to our present question: "What is human?" And here it would seem that, by science's own standards, if the world of natural events is not to be anthropomorphized, then the anthrop is not to be naturalized! Existentialism is most eloquent in this argument, but we must

surely see in every attempt to account for human behavior a kind of teleology being espoused; or at least a good deal of theoretical effort put into a substitute for this kind of description. Continuing in this vein, it would seem to us that to be human is to be responsive to final causation.

But how is this to be conceptualized? Is it not unquestionably certain that man responds to his past antecedents? Does not learning fashion his present behavioral predilections? Without denying the fact of antecedent events we must point out that antecedents can be such things as the Adlerian "life plans," which are, when put into effect, done so "for the sake of" their intended goals. But are these not simply mediators, plans themselves put into the so-called human being just as mediating stimuli are programmed into a rat? The final rejoinder here is: "No, not if meanings are bipolar and man as a human animal can reason dialectically. If this is true then that state of 100 per cent control from outside the organism that theorists like Skinner speak about is flatly impossible." Hence the heuristic device that a theorist *must* fall back on at some point if he is to ascribe humanity to man is the dialectic. One cannot program an animal that reasons by opposites!

So, in closing this chapter, it would be our argument that the term "personality" is superfluous without the predicate assumptions of a humanly dialectical intelligence, which can take in meaningful experience, consider alternatives by way of opposite implication in this experience, and then

project a plan, hypothesis, goal, aim, intention, purpose—call it what you will! —"for the sake of which" it behaves. This behavioral pattern is not simply the result of control, nor is it even mediated behavior. Rather it is created, conformed to, and premised upon. Here again the reader is under the persuasion—*not* the control—of a neo-Kantian theorist. He can reason to the opposite of the argument now being summarized, and—we firmly believe— come up with an alternative that will best suit him. But if he can do that, he can also "be" a distinct, unique person. Terms used to describe him in these creative efforts are properly thought of as personality concepts.

Chapter 7

The Family of the Psychiatric Patient

Donald A. Bloch

Introduction

This chapter will consider the relationship between a set of events usually thought of as being characteristic of a single individual, his psychiatric status, and events taking place in a natural social group, his family.

Interest in the family *of* the psychiatric patient has blended in recent years with an interest in the family *as* the psychiatric patient. As a therapeutic modality, family therapy originated in child psychiatry, drew important technical skills from play therapy, group therapy, and psychodrama, with more recent additions from the encounter and training group fields. On the theoretical side it has drawn much from psychoanalytic theory, from anthropological and sociological studies of the family and of small groups, and, more recently, from cybernetics, general systems theory, linguistics, and kinesics. While the family field has burgeoned in the last two decades as a

therapeutic and social movement, it is conceptually diverse and varied. As to practice, there are no generally accepted standards of certification or accreditation, and there is no national organization of family therapists; teaching in the field goes on in many different settings: medical schools, family institutes, freestanding workshops, in-service training programs of social work and mental health facilities, and graduate programs of departments of psychology.

This diversity can be found at all levels of theorizing, research, clinical conceptions, and therapeutic management. In this survey we will attempt to present the main elements of this array. In doing so we will focus on the following issues:

1. The Concept of the Psychiatrically Relevant Family

2. Categories of Definition of the Relation of the Family to Psychiatric Disorder

3. Psychiatric disorder as an exogenous stress on the family

4. Psychiatric disorder as caused by pathogenic relationships in the family

5. The family as a pathogenic culture carrier

6. Psychiatric disorder as an expression of the systems properties of the family

7. Family Characteristics Related to Specific Psychiatric syndromes

8. The Psychiatric Future of the Family

The Psychiatrically Relevant Family

An anchoring concept used in this essay is that of the *psychiatrically relevant family*, a term used to delimit a natural social system, based upon, but not limited to, the nuclear family. The psychiatrically relevant family may be defined along two principal dimensions, structure and function. By the first term we refer to the *structural units of the family* held in any given instance to be of psychiatric interest, for example, the mother-child relationship, the oedipal triangle, the nuclear family, the household, the three-generational family, the kin network. This is essentially a temporo-spatial definition. By function we refer to those aspects of *family interaction or process* considered of psychiatric interest, for example, role definition, power distribution, communication patterning, identity formation, intergenerational relationships, anxiety sources, defensive strategies. Naturally structure and function here, as elsewhere, are interrelated aspects of the same phenomenon.

The concept is necessary because of the wide variation in definitions of the family from culture to culture, from science to science, within any single science, and from one to another psychiatric problem. Thus relevance

necessarily expresses the *ad hoc* nature of present psychiatric studies of the family. Target symptoms, syndromes, attitudes, or traits are used as the defining elements in regard to the disorder being considered, as well as to define related characteristics of the family. As Leichter says, ". . . the family unit may shift according to the purpose of analysis." It follows that the psychiatrically relevant family should be thought of as a distinctive social unit that may or may not overlap other defined families. Legal, sociological, and anthropological definitions of the family, among others, are useful as definitional starting points in any culture, but such "families" rarely are congruent with the family of interest to the psychiatric theoretician or practitioner.

The starting place for most definitions is the nuclear family[1] (often referred to as the isolated nuclear family); that is, biological parents and children, generally considered in Western society to occupy the same household until the departure of the children in young adulthood to establish new families of their own. Although this is what is most often referred to as the family, it is unsuitable as a definition of the psychiatrically relevant family in many instances, since it may not conform to the group actually dealt with by clinicians; it does not take into account the wide variation in family and household composition, even in Western industrial societies; nor does it indicate the extent of that family that is psychologically meaningful to the individual.

A structural delimitation of the boundaries of the family may begin by noting the *temporal* aspects of such a definition. The outer limit of personal psychosocial time probably extends backward for four generations and into the future for three generations. Even for the neonate the family extends backward in time; there is a specific *familial* inheritance that is part of the psychosocial matrix into which the new human is born. Naturally the more remote in time, the less influential persons and events are; death and other dislocations alter or obliterate their idiosyncratic influence, and they are finally perceived as part of the general cultural inheritance. With the development in the individual of a sense of a personal future, the family comes to have a meaning as an extension forward of these unfolding processes. Although the extensive branching network of progenitors and descendants can hardly ever be assessed in detail, nevertheless, it is in this matrix that family themes, myths, identity positions, conflicts, and defensive positions are elaborated and synthesized. In connection with the temporal aspect of the family, its constantly changing character over time must be mentioned. Not only does the family have a past and a future, but also it is eternally flowing into new forms, monitoring and processing the developmental changes of its members and of the systems exterior to it.

Thus the psychiatrically relevant family is historical in nature, developmental and changing in character, multigenerational in structure. In addition, it has varying structural boundaries at any single point in time.

The most common subunit of the family of clinical interest is the marital pair. Without regard to the nature of the presenting problem, the husband and wife are most often apt to be considered as the primary unit of interest. If the group is enlarged, one child may be added, usually the identified patient, or the entire nuclear family may be included. Astute clinicians are sensitized to the defensive exclusion of a particular family member, often one child, from the therapeutic enterprise on the grounds that this person does not need to be involved, or will be damaged by exposure to secret or painful material, and are apt to insist that all members be included.

The issue may be conceptualized differently so as to include as "the family" all members of the household; practically this often indicates who is actually available for therapeutic work. This definition is particularly useful where cultures do not adhere to the nuclear model, and in situations where other persons have been regular and meaningful members of the household (a housekeeper or maiden aunt, for example).

Kin other than the nuclear family are often considered as important and within the bounds of relevance. Most commonly the parents and the siblings of the parents of the nuclear family are included. Many theories of transmission of pathology within families depend on a three-generational model, regarding as critical the necessities imposed on any one generation by the need to mediate and deal with issues originating in previous generations.

Ackerman, for example, has emphasized the issue.

Other components of the extended kin network may be included as part of the psychiatrically relevant family as well. Bell discusses four aspects of extended kin articulation with nuclear families. In the first two, extended families serve as countervailing forces, or as continuing stimulators of conflict; here the dynamics of intergroup relations are dealt with. In the second dimension the extended families act as screens for the projections of conflicts, or as competing objects of support and indulgence; here the social psychological qualities of the relationships are being dealt with.

Finally there is a kind of conceptual enlargement of the family system that extends the concept of relevance to other systems with which the family interacts and of which it is a part. The important instances of this are network therapy and ecological therapy. In the first instance relevance is extended to include members of the social networks of which the family is a part; friends, extended family, neighbors, and involved professionals may meet as a group with the therapist to consider the psychiatric problems of one member of that network (Speck and Attneave).

Other workers are more systems-oriented in their conception of the boundaries of relevance. Auerswald, in this connection, speaks of the ecological approach. Typically such therapists include representatives of all

social institutions that are believed to have power or to provide an important maintenance function for the family, such as the school, hospital, court, and welfare department. Thus in these approaches the nuclear family is considered not only as a system in its own right, or as part of an extended family system, but also in relation to its external boundary with other natural social institutions.

Categories of Definition of the Relations of the Family to Psychiatric Disorder

It is possible to classify views of the relations between psychiatric disorder and the family into several distinctively different categories. Each of these categories suggests a differing causal or etiological connection between the two and implies quite different management or therapeutic strategies. The variation between these categories is so great as to suggest profoundly different conceptions of the nature of the phenomenon of psychiatric disorder. Fully coherent and integrated statements of these positions do not exist, nor will exponents of one view hold to it in all circumstances. Depending on the purposes of the moment and on the material at hand, there may be some shifting back and forth between orientations. Nevertheless, the positions are distinctively different; those preferring one view are unlikely to vacate it easily.

Psychiatric Disorder as an Exogenous Stress on the Family

This view of the relation between the family and psychiatric disorder holds that in a particular case there is no substantial connection between the disorder and the family except insofar as it is a misfortune accidentally impinging on that particular context. An analogous situation would be a physical illness that in no way is related to the character structure of the family members or its health practices—a brain tumor, for example. There is taken to be no etiological connection, and the family issues to be dealt with are thought of entirely as reactive to the event.

The ability of the family to cushion the blows of adversity upon its members is an essential capacity. Stresses originating at other systems levels may impinge upon a family as crises that are dealt with successfully. A death adequately mourned, a disaster coped with or endured, a developmental crisis integrated through personal and group growth—these are all instances of the family healing its own members and protecting its own structure in the face of external pressures.

As a man in his seventies lay dying of cancer, lie requested a physician nephew to visit him. Barely able to speak, the dying man asked the physician in his presence to inform the wife and only daughter that his condition was hopeless. For the first time they were able to openly weep together and begin the process of leave-taking and mourning. In this instance, the extended family could be used to help heal the nuclear family by facilitating available

restitutive processes.

Some of the complexities of this model can be seen when one considers how psychiatric disorder itself is to be understood. Is it a stress upon the family system that requires adapting to; is it to be understood as an adaptation in and of itself to strains originating elsewhere; or is a blend of both views perhaps most appropriate.

Early psychiatric interest in the family assumed the disorder to be accidental, to arise endogenously in the patient, and, in its own turn, to pose problems for the family growing out of the need to manage the ensuing difficulties. The era of modern clinical study of the family began when this view was challenged as being universally applicable.

Psychiatric Disorder as Caused by Pathogenic Relationships in the Family

The bulk of research aimed at discovering the causal relationship between family issues and psychiatric matters has been carried out in terms of a model of linear causality. The underlying assumption is that a sufficiently homogeneous psychiatric entity can be delimited and that specific parental attitudes, traits, or practices can be located, most often in the mother, that cause this. The earliest versions of such studies indicted a blend of physical and social heredity as being pathogenic; for example, Dugdale's study of the Jukes and Goddard's study of the Kallikak Family.

Psychoanalytic theory, at about the same time —that is, at around the turn of the century— added the important dimensions of relationship and developmental vulnerability as being pathogenically critical. Freud's cases of Dora and Little Hans are discussed below. Subsequent psychoanalytic literature has richly developed these themes.

In the 60 years from 1910 to 1970 an extensive literature has developed in this field. Excellent reviews are to be found in Spiegel and Bell and Aldous and Hill. More recently Walter and Stinnett reviewed the literature of the 1960's on parent-child relationships. They found "a distrust of simplistic explanations concerning the direction of causality in explaining the nature of parent-child relationships." This includes a greater interest in contingent explanations and in qualified generalizations; even the direction of assumed causality is questioned. They quote Kysar as to the possibility that disturbed children may produce impaired functioning in their parents, rather than the other way around. The authors note a shift in the studies reviewed from an earlier almost exclusive concern with mother-child relationships to greater interest in fathers, although they note that the father-son relationship is explored much more than that of fathers and daughters.

They find that boys seem to be more susceptible than girls to parental influence, that "parental warmth is a factor which influences occupational choices among children as well as their academic achievement, leadership,

and creative thinking. Poor parent-child relations on the other hand, are related to aggressive, antisocial behavior, and a tendency for children to be involved in disciplinary action. Extreme parental restrictiveness, authoritarianism, and punitiveness, without acceptance, warmth and love, tend to be negatively related to a child's positive self-concept, emotional and social development."

The principal feature of the model being used is that a parental trait or attitude (Levy's maternal overprotection or Bowlby's maternal deprivation are good examples) is damaging because of some direct linear effect it produces on the child. The model is that of medical pathogenicity. The maternal overprotectiveness, for instance, is abstracted from the systems of which it is a part, such as a particular cultural attitude toward women and motherhood, a mode of mate selection, a multigenerational context, a pattern of parental relatedness, the mutual circular reinforcing programming of mother and child, and dealt with as if it existed in isolation and *caused* the pathological response to appear in the child.

If the wrong attitudes, traits, and practices can cause psychological illness in the child, it is reasonable to hope that one can discover these wrong attitudes and, having discovered them, teach parents how to do better. Out of such hopes has grown the broad field of parental attitude and child development research, as well as the influential child study movement in the

United States, which, in its political impact and in molding social attitudes, has done much to create the current climate of childrearing practices. While still an active social influence, this movement seems to be reducing its impact. The research yield has decreased considerably as well although the research model is attractive to students, because it lends itself to simple designs and straightforward quantification.

The Family as a Pathogenic Culture Carrier

As might be expected there have been heavy sociological inputs to this field, and investigators and theorists alike have attempted to use the language and research methods of sociology to elucidate the origins of psychiatric disorder in the context of the family. Bales, Bell, Bell and Vogel, Cottrell, Foote and Cottrell, Handel, Handel and Hess, Hare, *et al.,* Parsons and Bales, Spiegel, and Spiegel and Klyckhohn may be mentioned as seminal. The field is vast, and it is only possible here to indicate the general direction research and theorizing takes.

As part of the larger Stirling County Study, Cleveland and Longaker, using the research setting of a rural clinic, investigated neurotic patterns of interaction in a single family. Essentially the approach is sociological and consists of an attempt to relate the problems of the individual, "to certain important features of his personality (needs), to behavior expected of him by

the society (role) and/or to difficult and conflicting patterns of cultural prescription (value)." At the same time the cultural patterns of childrearing and modes of socialization are considered, with particular emphasis on interpersonal devaluation as a preferred socialization mode incompatible with the needs, role, and value system requirements of the culture. The authors' view is that the family mediates these constraints and that individuals are "in some sense trapped by the conflicting tenets of these two broad paths of life" (p. 171).

The predominant analytic model here is sociological; the family for the most part is seen as a straightforward social transmission conduit, with emphasis on role and value conflict and the use of a learned socialization technique—disparagement in this case—as a way of coping with these conflicts. In this view neurosis in an individual is precipitated as an immediate response to excess stress, such as organic illness, that makes untenable a previous integration of needs, role, and value. In analysis of this sort the family is seen primarily as an acculturator and socializes The larger society provides a range of options as to how these functions can be accomplished. Presumably a set of constraints, deriving from the nature of man in general and his procreative, nurturant, developmental, characteristics in particular, operate to determine the final course of these events.

It is necessary, of course, to take into account the particular features of

each homogeneous subculture. Vassiliou has attempted to deal with the cross-cultural issue by the use of the concept of milieu specificity. In an article on this subject Greek culture and the historical development of the modem Greek family is reviewed, leading to a picture of the contemporary Greek family. "Man-woman relations are characterized by superordination of the man, mutual ambivalence, and ingratiating and contemptuous attitudes of women toward men." There is a great emphasis on "proper" marriage, with clear role ascription.

Milieu specificity refers to the particular way in which needs or wishes, presumably panhuman, tend to play themselves out in the specific cultural situation. Attempting to combine the psychoanalytic and sociological points of view, the author uses such terms as penis envy and castration anxiety to indicate these needs and points out how the specific interaction within Greek family life modifies their unfolding.

Miller and Westinan describe a mode of analysis of marriage and family that is based, in the beginning, on the partner's identities, subidentities, roles, and social positions. Identity is defined in terms of both self-identity, that is, how the person views himself, and the objective public identity, that is, how he is viewed by others. The sociological term "altercasting" is used to describe the pressures exerted on others to assume a particular subidentity, presumably complementary in nature. A general theory of pathology is

developed based on the degree to which there is compatibility between experience and subidentities. Thus the effeminate husband may be expected to show masculine initiative on his job and be subservient at home. A newborn child may act as a stabilizer, or may tip the balance toward instability, because his presence "requires the development of new sub-identities in parents and siblings."

The family as acculturator may induct its members into roles, value systems, and perceptual-cognitive modes that deviate from those of the larger culture. The dominant culture may define these deviant ways as "sick," "criminal," or "defective"; this labeling, in turn, may be regarded by the subordinate culture as political scapegoating. A recent instance may be found in the controversy over the Moynihan Report. This report contended that an important proportion of black families were enmeshed in a particular version of the culture of poverty, growing out of the heritage of slavery days. Moynihan believed that these black families were caught up in a self-perpetuating pattern of female dominance, female economic power, together with male impotence and extrusion from the family. This was related to the systematic attack on the masculine role in the black family in slavery, with the development of a protective matriarchy. Discriminatory social, educational, and employment practices in industrial society were held to undermine further the position of the black male, with the consequence that a vicious generational cycle was established and maintained. Critical to this conception

is the notion that the self-image for both sexes is distorted and that family relationships and child-rearing practices are so structured in a hostile white world as to maintain the pattern.

Critics of the report note that there is no such thing as a "homogeneous and perdurable" white family unrelated to class and culture; that even if there were it is questionable if it should serve as a paradigm, or if it "actually possesses the virtues attributed to it. . Blackness is minimized as etiological in these critiques and poverty emphasized.

Aside from the substantive merits of these arguments one must note the political importance attached to allegedly scientific assessments of family functioning.

Psychiatric Disorder as an Expression of the Systems Properties of the Family

A promising recent theoretical approach to understanding the family comes from general systems theory. Originally this approach was developed by von Bertanlanffy, a biologist, who pioneered the field in the 1940's. Systems approaches consider phenomena as part of networks of circular causality rather than in terms of linear causality. It is an organismic approach where self-regulating mechanisms are the essential building blocks. Thus it is uniquely suited to dealing with living systems. To think of the family in this way is to ask how it can be conceptualized as a set of structures organized so

as to maintain patterned integrated functioning of the entire system.

Roy R. Grinker, Sr., notes that "general systems theory includes concepts of integration and process by which integration is maintained in all open living systems inescapable from their environment. Each system is composed ... of sub-systems under control and regulation within specified gradients. Information exchange occurs among sub-systems, and between systems, at their interfaces by means of reverberating circular transactions" (p. 135). These words felicitously introduce the notion of information exchange.

All energy transformations can be conceptualized as information exchanges as well and understood in terms of the thermodynamic laws. The family, in this sense, is an open system in that there are transactions across its boundaries of information, or energy. The family as a system makes up a set of interfaces with other social institutions and can be characterized then as to the nature of these interfaces and the transactions taking place across them. Among these social institutions would be other parts of the larger kin network, other families, educational systems, medical care systems, and mental health intervention systems.

Internal subsystems of the family include generations, the parental pair, and sex splits, among others. In all of these instances the same principles of interface and information exchange across it apply.

Perhaps the keystone systems concept used by family therapists is that of homeostasis, the tendency of the organism or system to dynamically and actively re-equilibrate itself. Homeostasis, or homeodynamics as Ackerman calls it, has been a conceptual tool of considerable importance to the clinician in the field of family studies. It serves as a reliable guide to understanding mechanisms resisting therapeutic change. Simple examples include roles or identity positions that must be filled in the family. Speck notes that when a suicidal patient gives up his self-destructive ideation, his role in the family will be replaced by the appearance of a depression in another family member. It is as if the equilibrium in the family can only be maintained by the presence of some expression of this affect. Perry, *et al.*, observed that families in a disaster acted as a unit to maintain one parent in the strong protective role and suffered severe anxiety when this no longer could be accomplished. Rashkis noted the importance of depression in maintaining family homeostasis, and numerous other observers, Jackson most importantly, have spoken on this issue.

It is possible to conceptualize new family formation in systems terms in part as an effort by each partner to reproduce in dynamic terms the configurations and interchanges experienced in the family of origin. Tomas has called attention to the importance of sibling position in dynamic terms as a factor in mate selection. Napier speaks of this process as cross-generational complementarity. He describes the matrix of complementary expectations to

be filled by the mate, matrices that have developed in the context of the homeostatic requirements of the family of origin. Finally Erlich and Bloch describe therapy in terms of the transaction of two family systems, that of the patient and therapist, as each struggles to integrate old themes (parameters) in the new therapeutic relationship. They point out the similarity, in systems terms, between the new pair formation of therapist and patient and mate selection.

Family Characteristics Related to Specific Psychiatric Syndromes

Investigators attempting to relate dimensions of family life to pathology have approached the issue in ways that reflect their personal biases, professional technologies, as well as the special nature of the problem being studied. Clinicians in recent years have considered almost all of the well-defined psychiatric entities from the family point of view. In a number of instances rigorous, quantified research has also been conducted.

Schizophrenia

Understandably families with schizophrenic members have attracted great interest on the part of both clinicians and researchers. In the same spirit that has led other investigators to search for a unitary cause for this "disease," family researchers have tried to define the uniquely pathogenic qualities of

the family with a schizophrenic member. While the hope of finding the specific family etiology of the disorder seems clearly illusory, there have been a number of significant contributions to a better understanding of the syndrome.

Overall these studies have become increasingly sophisticated, developing more meaningful typologies of families with schizophrenic members based on the sex, premorbid history, quality of thought disorder, and social class of the index patient.

One group of studies may be broadly characterized as having a psychoanalytic orientation. Alanen, for example, offers a developmental conception beginning with "the defective initiation into important object relations, above all that with the mother." Davis attempts to get at the oedipal contribution to the etiology of schizophrenia in males. In acute schizophrenic breakdown he claims that anxiety arises out of the relationship with the mother and "the illness begins when a change in this relationship increases the anxiety. The frustration of incestuous wishes contributes to this anxiety." This is associated with "a failure of identification with the father, a poor relationship between mother and father. . . ."

The most important studies of this genre are those of the Lidz group at Yale, which reports on investigations of middle-class, structurally intact

families with schizophrenic young adult members. Middle-class families were chosen for study so as to avoid the effects of social disorganization under economic stress. There were many clinical contacts with the families and with kin, friends, servants, and so on. In addition to clinical interviews at home and in the hospital, a complete battery of psychological tests was administered. To summarize their findings, all families "were severely disturbed, distorted by conflict, and beset by role uncertainties by family members other than the patient."

Patients' mothers appear severely disturbed, often bordering on the psychotic, but without a single predominant personality type, rather showing a wide range of disturbance. The authors underscore the importance of the fact that these women were "paired with husbands who would either acquiesce to any irrational and bizarre notions ... or who would constantly battle with and undermine an already anxious and insecure mother."

The fathers in half the families were described as paranoid, "paired with a submissive acquiescing spouse. . . Again there is no "characteristic type of disturbed father," but a general inability to play the paternal role successfully for a variety of reasons. The suggestion is that if they had married more supportive wives, they might have done better as fathers and husbands. The Lidz group's findings seem comparable with those of Cheek, who says, "The profile of the father of the schizophrenic differed less from that of the father

of the normal than the profile of the mother of the schizophrenic differed from the profile of the mother of the normal." Cheek agrees with Parsons to the effect that "schizophrenia may be related to a lesser differentiation of parental sex roles in the family." However, he notes, "Our study does not tell us whether or not this distortion of parental roles has been a cause of, or a reaction to, the schizophrenia."

In the Lidz studies two types of families are described. Schismatic families are "beset by chronic strife and controversy, primarily between the parents. . . . The parents undermine each other's worth, despising each other as man or woman, depriving each other of much needed support. . . This is particularly important in that it raises severe identity problems for the children.

The second type of family they describe is the skewed family, which may be peaceful on the outside, but where the peace is maintained because the parents have "overtly or covertly reached a compromise concerning a serious personality defect in one or the other." (Wynne's pseudomutuality and Laing's mystification are related concepts.)

Considering the difference between families in which a male rather than a female becomes schizophrenic, they note, among other things, that same sex siblings seem to be more disturbed than opposite sex siblings. Three issues

appear to be critical: "(1) the faulty model for identification provided by the parent of the same sex as the patient; (2) the impediments to proper resolution of the patient's oedipal attachments, created by the disturbed parental interaction; and (3) the failure of the parents to maintain proper generation boundaries between themselves and the patient, either by being seductive with a child or by being more like a rivalrous sibling than a parent, with both patterns sometimes occurring in the same family."

Considering the influence of parental homosexual tendencies, Lidz and Lidz points out, "The de-erotization of the child-parent relationship is one of the cardinal functions of the family," and in a series of cases they illustrate the failure to accomplish this in the mother-daughter relationship. In these families this failure increased the insecurities of the child, who focused on a complex and perplexing tie to the mother as a mode of maintaining security.

Turning to the central problem in schizophrenia, the nature of the thought disorder, they say, "We are following the hypothesis that the schizophrenic patient escapes from an untenable world in which he is powerless to cope with insoluble conflicts by the device of imaginatively distorting his symbolization of reality."

The mother of a schizophrenic son is seen as needing the son to complete her frustrated life. She demands the impossible from him, feels only

he understands her, and excuses all difficulties as being the fault of some other person or institution. A hopeless enmeshment is created for the child, nor is there any exit from this because of the qualities of the father.

The Lidz group speaks of folie a famille where the life of the family centers around the distorted beliefs of one parent, usually the father, and lives according to a social pattern quite different from the larger social context. The parents hold a rigid and fantastic conception of the environment and the family into which the children must fit without regard to reality or their own needs. These parents are described as being "impervious," unable to hear the child's emotional needs, and, in general, much given to projective identification, the attribution to the child of the parental needs, principally in the service of maintaining the parent's picture of himself and of simplifying a complex environment.

Lyman Wynne and his co-workers set themselves the formidable task of trying "to develop a psychodynamic interpretation of schizophrenia, that takes into conceptual account the social organization of the family as a whole." They build their theory on the need of all humans to be related and on the striving to develop a sense of personal identity. The attempt to deal with these issues may lead in three directions: mutuality, nonmutuality, and pseudomutuality. The latter they regard as occurring widely and consisting of a "predominant absorption in fitting together, at the expense of the

differentiation of the identities of the persons in the relation." The essential difficulty in differentiation of identity characterizing the schizophrenic is put this way: "There is a characteristic dilemma: divergences are perceived as leading to disruption of the relationship . . . but if divergence is avoided growth of the relation is impossible." Under these circumstances noncomplementarity, that is, individuation and separation, must be avoided at all costs since it is the most severe threat in these families. Thus, in terms of the development of the schizophrenic modes of life, important motivational systems must be excluded in the spirit of maintaining the appearance of mutuality.

For a variety of reasons, including the painful experience of separation, there is held to be a strong drive toward maintaining a *sense* of relation. The inevitable discontinuity of relatedness in situations of even minor conflict or disagreement cannot be tolerated. Genuine mutuality leading to the growth of the relationship through the exploration and enlargement of alternative modes of interacting cannot be achieved because of the underlying rigidity and fragility. The authors emphasize the role rigidities of these families as well as the absence of imaginative play or affective release in the interactions of family members. Noncomplementarity is seen as being the most serious threat.

Shared mechanisms operate within the family to maintain this

pseudomutuality, including the nonrecognition or delusional reinterpretation of any deviations from the rigid family role structure. A consequence is that differentiation and individuation are severely impaired and that it is extremely difficult for the members of these families to distinguish the family boundary. The term used for this by Wynne is "the rubber fence," an "unstable but continuous boundary, with no recognizable openings, surrounding the schizophrenic family system, (which) stretches to include that which can be interpreted as complementary and contracts to extrude that which is interpreted as noncomplementary."

According to Wynne and his co-workers, "The fragmentation of experience, the identity diffusion, the disturbed modes of perception and communication . . . are to a significant extent derived, by processes of internalization, from characteristics of the family's social organization." In this regard it is possible to see the similarities between the Lidz and Wynne approaches to these issues. Assisting in the formulation of these theories is the subjective experience of the therapist in direct work with these families (Schaffer, *et al.),* an experience that "tended informally to be reflected in the use of words such as maddening, enraging, bewildering, and exhausting. . . ." The sense is that a pattern is established of idiosyncratic meanings within the family that are destructive of meaning to those unfamiliar with the premises and logical interrelationships.

Wynne and Singer attempt to relate schizophrenic thinking disorders to family experience in more detail by a more refined assessment of the nature of the thinking disorder. Clinical observations were "concerned with the styles of focusing attention and communicating in these families, which may have a disorganizing, complementary effect, or may provide models which are internalized in the same form into the ego structure of the growing offspring."

Wynne and Singer's study used parents of childhood schizophrenics, adult schizophrenics, acting-out children, and withdrawn, neurotic children. When the Rorschach and TAT tests of the parental pair were compared, blind ranking of these tests showed high correlation with the diagnosis of the child. Moreover, it was possible to relate the distinctions between the groups to a cognitive style and experiential mode that might be understandably related to the child's pathology. Thus on the TAT parents of autistic children "have clear percepts; depict people, events, feelings, consequences clearly, compared to parents of adult schizophrenics," who "have people, events, feelings, consequences remaining global, abstract, overly general, attention appears fragmented or amorphous." This would support other findings (Goldfarb and Meyers and Goldfarb, as well as those of Reiss on cognition), distinguishing families of autistic children as being comparatively less pathogenic.

Laing has advanced the view that pathology lies, as it were, in the eye of the beholder. As he sees it, this is true for individual psychopathology, and

even more so for the concept of family pathology: "It extends the unintelligibility of individual behavior to the unintelligibility of the group," With various co-workers Laing has constructed an experiential approach to individual and family psychodynamics. Dyads, triads, and more complex networks, of which each individual is a part, are related by mutual percepts and in layers of further complexity, the perception of the perception of the perception. A unique reality is constructed thereby, which is true for the particular individual and family; this reality is to be discovered in the therapeutic work, especially the processes whereby contradictions and illogicalities are reconciled.

One such process of key importance in Laing's thinking is *mystification.* Laing emphasizes that mystification is both an *act* and a *state* and points out that the person being mystified may not know it or feel it. It is a process operating within the family (and elsewhere for that matter) in which the person is systematically forced to deny data from one realm in the interest of maintaining a percept or relationship. Relating mystification to the double-bind concept Laing notes, "The double-bind would appear necessarily to be mystifying, but mystification need not be a complete double-bind" (p. 353).

An extensive case report embodying this point of view can be found in Schatzman. In this paper the Schreber case, which played a key part in the development of Freudian psychoanalytic theories of paranoia, is reviewed,

with emphasis on the use of mystification to cover over deeply conflicted issues in the relationship between Schreber and his father. Schatzman concludes that Schreber was indeed persecuted by his father and mystified in addition, by being told the persecution was loving. His delusions then represented an effort to make sense out of this total configuration.

Bateson, Haley, Jackson, and Weakland aim to develop a communicational theory of schizophrenia. The cornerstone propositions are that learning occurs in a context that has formal characteristics and that this context always occurs within a wider context called a metacontext, indeed, within a series of these.

Bateson says, "Even more shocking is the fact that there may be infinite regress of such relevant contexts." There is a relationship between context and metacontext that may be congruent or incongruent. Metamessages tell the receiver what the relationship is between messages of different levels, with the possibility that "in human relations another sort of complexity may be generated; e.g., messages may be emitted forbidding the subject to make the meta-connection."

Bateson, Jackson, *et al.,* discuss the relationship between family homeostasis and schizophrenia in communicational terms. The essential feature of this relationship is the *double-hind,* described as a repeated

experience in which a person (called a victim) is subjected to messages containing a primary negative injunction, such as "do not do so and so, or I will punish you," together with a secondary injunction at a more abstract level, which conflicts with the first. It is essential that the "victim" also be prevented from escaping from the field. The authors suggest that an individual repeatedly exposed to this mode of communication will suffer a "breakdown in his . . . ability to discriminate between logical types, … in a double-bind situation, a shift to metaphorical statement brings safety." This use of metaphor often corresponds to what is called psychotic behavior.

Specifically, in regard to the family situation in which these events occur, the authors suggest: "1. The child's very existence has a special meaning to the mother, which arouses her anxiety . . . when she is in danger of intimate contact with the child. 2. The mother's way of denying this anxiety and hostility is to express overt loving behavior. 3. There is no strong insightful person available to the child to support it in the face of the contradictions." The emphasis throughout is on the child's being forbidden to discriminate the metacommunicative messages, which are inherently contradictory. As the authors note, the child "must deceive himself about his own internal state in order to support mother in her deception."

Analyzing the communicative pattern of schizophrenics in this context, Haley emphasizes that various kinds of *disqualification* occur in messages; for

example, that the person is not really the source of the message, that the words are action and not really the message, that the receiver is not really being talked to (this emphasizes the self-negating quality of paranoid statements). The emphasis here is on the schizophrenic's effort to extricate himself from the family communicational pattern and on the conceptualization of the schizophrenic symptoms in those terms. "It can be argued that psychotic behavior is a sequence of messages which infringe a set of prohibitions but which are qualified as not infringing them." Haley emphasizes the degree to which the disqualification process avoids the risk of accepting being governed by other people and that this, in turn, destroys relationships.

Reiss performed a series of experiments aimed at distinguishing the cognitive styles of families with normals, character disorders, and schizophrenics. Five families in each group were tested by a series of experiments; a chief feature of which was to distinguish the degree to which intrafamily cues and ideas were attended to rather than those coming from outside the family. Schizophrenics were distinguished for their attention to intrafamilial cues. This finding is commensurate with the unique and idiosyncratic information environment within the family containing a schizophrenic person.

In an effort to distinguish efforts due to socioeconomic status, the

relation Rorschach, in which several family members are asked to compose a response to the Rorschach card, was used to study 17 black schizophrenics, 11 white schizophrenics, and 11 lower-class black control families. The transcripts of the tests done in the homes were studied by raters who did not know the families. The results "indicate the communication and interaction patterns of lower-class families with a schizophrenic differ in a significant way from these patterns in families whose class background is similar, but which do not contain a schizophrenic." Interestingly a distinction could *not* be made in regard to the white and black schizophrenic groups.

Many studies, have investigated the relation between the spouses of schizophrenic persons. Becker, for example, found that the husbands of schizophrenic wives generally came from materially and emotionally deprived backgrounds, with duty-bound, close ties to harsh, demanding fathers and affectionate mothers. It often seemed as if these husbands did not find it possible to separate from their families of origin in order to make strong ties with their wives. This led to frequent neglect, increasing with the birth of new children, which often, in turn, led to schizophrenic breakdown in the wives.

DuPont and Grunebaum point out that paranoid women tend to marry men who are walled off, passive, and unable to express hostile or erotic feelings. In some instances the wife's psychosis is precipitated by the

husband's reduction in sexual activity. They point out that the husband's "eagerness to reunite with his wife and to exclude others was reflected in his failure to support her therapeutic alliance with her psychiatrist and his failure to consider divorce."

Phobias

The case of "little Hans," first published by Freud in 1909, presaged later psychoanalytic theories of pathology in the family as well as techniques of family therapy. The identified patient, a five-year-old boy, is treated through the agency of his father, of whom Freud says, "the special knowledge, by means of which he was able to interpret the remarks made by his five-year-old son, was indispensable . . . and (treatment was possible) . . . because the authority of a father and a hand of a physician were united in a single person. . . .

Strean discusses this case as an early example of family diagnosis and treatment. In the same spirit the celebrated case of Dora can be read as an instance of symptoms appearing in one member of the family as a result of events occurring elsewhere in the family system. Here the identified patient is an 18-year-old girl, diagnosed as hysterical, with a nervous cough, aphonia, easy fatigability, and suicide threats. The precipitating event of her illness was her father's involvement with the wife of a business friend; the friend had on

one occasion made a sexual approach to Dora. Freud uses both of these cases to demonstrate the unfolding of psychosexual development; they are equally useful as early statements about the relationship between family interaction and psychopathology.

Repeatedly anxious, phobic patients are viewed as expressing affect present in other members of the family, often a husband or wife. As Fry has observed, "The spouses of the patients in this group . . . are typically negativistic, anxious, compulsive, and show strong withdrawal tendencies." Upon careful study the spouses reveal "a history of symptoms closely resembling, if not identical to, the symptoms of the patient. Usually they are reluctant to reveal this history." It is as if the symptoms of one (more severe) make it unnecessary to face the symptoms of the other. Frequent collusive involvement is seen. For example, the spouse will volunteer to stay with the anxious patient, even though the patient does not need or wish it.

Fry also notes, as does Carek and Miller, that symptoms seem to break out at a point when the spouse has some change— usually for the better—in his life; there is a constant dual supervision and control, and the couple are frequently held together by the symptoms.

Johnson, *et al.,* writing in 1941, described a pattern of generational transmission of school phobias, in which the mothers of children express "an

inadequately resolved dependency relationship to their mothers, with intense repressed resentments." In turn, their own children are pulled into a pattern of dependency, which is then shifted to the school, because of the differing patterns of authority there. "When the teacher, as a more consistent disciplinarian, frustrates the child, she arouses his rage." The child's rage toward the mother is inhibited and the teacher becomes the phobic object. In explanation a three-generational structure is invoked as well as comments about the specificity of interaction in the child's involvement with the school. The minimum systems model seems to include the child at an interface between his generational family and the school.

Ackerman reports a case of phobia in a four-and-one-half-year-old boy. He relates this to the mother's inability to establish close contact with the boy, her guilt, domination, inconsistency, overindulgence, and eventually his "frightened retreat from her oral, devouring attitude" (p. 119). The concept of homeostasis, as used by Ackerman, really concerns much more the homeostatic equilibrium of the self, rather than of the family.

Psychosomatic Disorders

Some psychosomatic illness seem clearly connected to aspects of family life. The connection has been made, for example, in certain cases of severe childhood asthma. Purcel, *etal*., note, "It is clear that substantial numbers of

asthmatic children admitted to hospitals lose their symptoms rather rapidly, while others show relatively little symptom change in response to institutionalization and separation from home." An effort was made to distinguish the two groups. An imaginative procedure was used, whereby the child stayed physically in his own home although all parental and sibling figures were removed, and a substitute parent was provided. The carefully controlled study showed that children with a history of emotionally precipitated asthmatic attacks were improved by removing the people from the house—even though the allergenic situation was unchanged.

Meissner, reviewing the problem of the connection between family processes and psychosomatic illnesses, notes that it is necessary to suggest "a link between emotional dysfunction related to psychosomatic illness and discernible patterns of family dynamics." The issue is not whether there is a connection between emotional stress and somatic disorder, rather whether there is some unique connection between family patterns and such disorder. Although research in this area has been relatively unproductive thus far, it is our conviction that several modes of investigation will fuse in the near future to improve our understanding of these relationships. Specifically it seems likely that kinesthesiologic studies of family interaction from the viewpoint of operant conditioning, using highly responsive physiological measures, will reveal the subtle modes whereby families teach somatic responses to their members.

Titchener, in a case study of a family in which one son developed ulcerative colitis, suggests, "The rigid and confining patterns of object relations were not only formed in the binary mother-child symbiosis, but were conditioned by the multi-dimensional matrix of object relations constituting the field in which his personality developed." Jackson and Yalom describe such families as being very restrictive with limited interaction, affectivity, and contact outside the family, and with a communicative restrictiveness through the generations.

Learning Difficulties

Grunebaum, *et al.*, studied the families of boys with neurotic learning inhibitions. They identified patterns of interaction between the parents that prevented the boys from adequately identifying with their fathers or from perceiving their fathers to be competent or worthy.

Similarly Miller and Westman noting that the mothers in these families exercise the real power, "postulate that parents and children resist change in the reading disability, because it contributes to the family's survival." The main line of analysis concerns the support for an identity based on the parent's projections. In addition, "The symptom and subidentity act as governors on aggression between the parents." When the symptom changes, there is increasing disturbance elsewhere in the family—evidence of the

homeostatic function of the behavior.

Delinquency

Ferreira explores the concept of the double-bind as it relates to delinquency and speaks specifically of "the split double-bind," where "the victim is caught in a sort of *bipolar message* in which A emanates from father, for instance, and B (a message about Message A) from mother." He notes the special importance for delinquency of *punishment* as a consequence of the efforts of the child victim to avoid the double-bind; each half of the parental pair threatens a series of punishments as the consequence for not obeying his half of the self-canceling message.

Addictive States

Ewing using concurrent group therapy for wives and husbands, notes that "marriage to an alcoholic is no accident. . . ." The wife seems to need a weak, dependent husband and sabotages efforts to improve his strength or accept her own dependent needs. One case is described in which there is a constant interplay between the husband's drinking bouts and the wife's depression, which requires hospitalization.

Homosexuality

Bieber, *et al.* conducted a study of 206 male psychoanalytic patients, of whom 106 were homosexuals. Brown's findings in his study of Air Force personnel, in regard to mother-son and father-son relationships, are confirmed here as well. The authors consider, too, the "triangular system," involving both parents and the son. The basic mode of analysis consists of "constructing classifications of mother-son, father-son, and interparental power-affect parameters." They find, "The classical homosexual triangular pattern is one where the mother is CBI (Close Binding Intimate) and is dominant and minimizing towards a husband who is a detached father, particularly a hostile-detached one. . . . Chances appear to be high that any son exposed to this parental combination will become homosexual, or develop severe homosexual problems" (p. 172).

Depression and Suicide

Various writers have related suicide and depression to characteristics of family systems, noting their transactional nature. Thus Goldberg and Mudd develop a categorization based on the notion that "in married persons suicidal behavior may be regarded as a transaction between the suicidal individual and his spouse." Essentially the threats and plans are seen as a move to maintain domination and control of the partner.

Speck is concerned with the homeostatic equilibrium of the family that

is maintained by the suicidal behavior and speaks of families who seem to hold to the dictum, "better mad than bad," citing case material where improvement in one member, the suicidal patient in this instance, produces an increase in seclusiveness and withdrawal in other family members.

Whitis, speaking of a child's suicide, observed, "The suicide served to spotlight the apartness each member of this family felt in this inability to communicate with one another in a helpful or constructive way."

The Psychiatric Future of the Family

Any assessment of the relation between psychiatric status and the family must recognize the influence on this issue of the rapid process of social change presently characteristic of the family in the Western world. As standards of normative behavior change, diversify, and broaden, the reference points used for judgments about deviation change. The social vantage point, i.e., bias, from which a psychiatric judge views phenomena determines the meaning of the behaviors being assessed. Also the very processes of rapid social change themselves, operating on families over time, have an effect equivalent to exposure to markedly different cultural sets and expectations. There is little reason to expect these factors to abate in the future; more likely their effects will intensify.

As a consequence it becomes even more difficult for the psychiatrist

confidently to assume that he knows the directions family life should take; yet it is not possible for him to abandon or deny his own value systems since they are the points of reference he must use in order to define behavior as psychiatrically relevant. This is especially so when he is dealing with cultures other than his own. The white view of the black family is notably deficient in this regard, as is that of the male psychiatrist judging the "proper" role for women.

The psychiatric future of the family cannot therefore be separated in any way from the broad processes at work to create change in society at large. A few of the more important of these processes may be noted. First, there is the rapid change in the status of women vis-a-vis men. Associated with this are profound revisions of the ideal and normative expectations of both sexes with regard to such family functions as childrearing, domestic work, and sexual intimacy. Patterns of pair bonding are changing rapidly; premarital sexual liaisons are openly accepted in many quarters, and the age of permissible sexuality is lowered on one hand and raised on the other. Adolescents and youth are expected to have active sexual lives prior to marriage, while the sexual needs and capabilities of the aged are better understood and accepted.

The contractual patterns of family life are changing, again in the direction of greater permissible variation. Illegitimacy as a status is becoming

increasingly obsolete, the singleparent family more common. Not only is divorce ubiquitous, less opprobrious, and easier to secure, but also unconventional household and childrearing arrangements such as group or homosexual marriages are becoming steadily more common and more frequently legitimized. Thus participation in a nonstandard family arrangement is no longer prima facie evidence of psychiatric disorder.

Demographic patterns are changing rapidly, again with profound impact on the nonnative expectations for the family. Deliberately childless couples are more common, and the birth rate has recently dropped (1972) to the lowest point in U.S. history, a rate approximating that needed to achieve the goal of zero population growth. Abortion laws are increasingly liberalized in the direction of abortion on demand; these, together with changed contraceptive technology and social attitudes, have markedly reduced the number of children available for adoption, increasing the movement into various forms of single-parent adoptions, cross-race and cross-religion adoptions, and the adoptions of children previously unplaceable by virtue of age or physical handicap.

Another demographic change of consequence for the family is the increased number of aged persons in the population. The generational splitting, age-grading, and emphasis on youth that has characterized much of recent U.S. social history has, when combined with patterns of increasing

longevity, produced many serious problems of social isolation in the aged. The primary breakdown in ties to kin networks results in an epidemic psychiatric public health problem. Differential mortality rates between men and women accentuate this; a pattern of marriage of women to men two or more years senior, when coupled with this differential longevity, statistically guarantees an increasing pool of older, isolated, sexually active single women.

There are no base lines established for rates of social experimentation in new modes of intimate relatedness. Thus it is only an impression that these are proliferating at a great rate;

the impression may in part be due to greater acceptance of public discussion of issues formerly barred. Constantine and Constantine, studying group and multilateral marriages, have been impressed with the large number of persons considering establishing such relationships in comparison with the small number actually doing so. Despite this it seems certain that the family of the future, and thus the psychiatrically relevant family of the future, will refer less often to the modal nuclear family of the past and with increasing frequency to a nonstandard pattern of relatedness. Perhaps most important in terms of the generational model that family psychiatry has found to be so helpful, the natural social system into which a person is born, the natural social system in which he lives his adult life and procreates, and the natural social system in which his children (if any) live their lives, all will be

different.

Notes

[1] In general terms family is a biopsychosocial system found in all cultures that acts: (l) to reproduce other families (Families reproduce reproductive units, namely families. It is the human biopsychosocial system that uniquely recruits new components by biological means, i.e., sexual reproduction); (2) to nurture and acculturate young humans; and (3) to care for some of the biopsychosocial needs of its members.

Chapter 8

The Concept of Normality

Daniel Offer & Melvin Sabshin

Introduction

Why has the study of normality and health been a relative newcomer to psychiatry? One obvious reason is that it is a result of training, since training produces not only a set of skills but also what Kaplan calls a trained incapacity. Trained to recognize the abnormal, the psychiatrist and his teacher have had difficulty in recognizing the normal. Recently there has been a surge of interest among mental health professionals in studying normality. In part it is important to study normality because it serves as a base line for all behavior whether pathological or not. Reference to the normal also gives empirical validation to theoretical constructions concerning any kind of behavior. That is not to say, however, that the concept of normality is a clear and concise one. On the contrary, the concept is ambiguous, has a multiplicity of meanings and usages, and is burdened by being value-laden.

In the past, within the behavioral sciences in general and specifically within psychiatry, there has been an implicit understanding that mental health could be defined as the antonym of mental illness. Given such an assumption, the absence of gross psychopathology was often equated with normal behavior. A number of recent trends have cast doubt on the usefulness of this assumption and have made it increasingly important for psychiatrists to become concerned with providing more precise concepts and definitions of mental health and normality.

As psychiatrists began to move out of their consulting rooms and hospital wards into the community, they began to come into contact with segments of the population not previously seen in their more traditional role functions. The broader acceptance of preventive, social, and community psychiatry has necessitated a re-examination of preventing *what* in *whom.*Psychiatrists have also become increasingly involved in agency consultation, where they are called upon to make decisions about who is healthier rather than about who is too sick for various positions. Interest in evaluating the outcome of psychiatric therapeutic endeavors has also brought the issue of what is mental health or normality into focus. Indeed, assessing therapeutic outcome has been handicapped by lack of clarity regarding the concepts of normality and mental health.

This chapter is written with the intent of clarifying some of the

conceptual issues related to normality and mental health. We cannot provide a definitive answer to the question, "What is mental health or normality?" since such an answer must eventually evolve out of new research and new experiences. Because cultural and personal values and biases are so intimately tied to one's conception of normality, it is doubtful whether, even in the long run, we will have *one*definition of normality. We shall attempt, however, to delineate the perspectives of normality, evaluate some of the current research on normal populations, and point to newer directions that promise to elucidate the issues still further.

The Four Perspectives of Normality

In our review of the literature on the theoretical and clinical concepts of normality, we were able to define what we called the four "functional perspectives" of normality. Although each perspective is unique and has its own definition and description, the perspectives do complement each other, so that together they represent the total behavioral and social science approach to normality. The four perspectives are (1) normality as health, (2) normality as utopia, (3) normality as average, and (4) normality as process. Let us now define these four perspectives in more detail.

The first perspective, *normality as health,* is basically the traditional medical psychiatric approach to health and illness. Most physicians equate

normality with health and view health as an almost universal phenomenon. As a result behavior is assumed to be within normal limits when no manifest psychopathology is present. If we were to transpose all behavior upon a scale, normality would encompass the major portion of the continuum and abnormality would be the small remainder. This definition of normality correlates with the traditional model of the doctor who attempts to free his patient from grossly observable signs and symptoms. To this physician the lack of signs or symptoms indicates health. In other words, health in this context refers to a *reasonable* rather than an *optimal* state of functioning. In its simplest form this perspective is illustrated by Romano, who states that a healthy person is one who is reasonably free of undue pain, discomfort, and disability.

The second perspective, *normality as utopia,* conceives of normality as that harmonious and optimal blending of the diverse elements of the mental apparatus that culminates in optimal functioning. Such definition emerges clearly when psychiatrists or psychoanalysts talk about the ideal person or when they grapple with a complex problem such as their criteria of successful treatment. This approach can be dated directly back to Freud who, when discussing normality, stated, "A normal ego is like normality in general, an ideal fiction." While this approach is characteristic of a significant segment of psychoanalysts, it is by no means unique to them. It can also be found among psychotherapists of quite different persuasion in the field of psychiatry and

psychology (for example, Rogers).

The third perspective, *normality as average,* is commonly employed in normative studies of behavior and is based on the mathematical principle of the bell-shaped curve. This approach conceives of the middle range as normal and *both* extremes as deviant. The normative approach that is based on the statistical principle describes each individual in terms of general assessment and total score. Variability is described only within the context of groups and not within the context of one individual. Although this approach is more commonly used in psychology and biology than in psychiatry, recently psychiatrists have been using pencil and paper tests to a much larger extent than in the past. Not only do psychiatrists utilize results of IQ tests, Rorschach tests, or T.A.T. but they also construct their own tests and questionnaires. Conceptually the normality as average perspective is similar to Kardiner's "basic personality structure" for various cultures and subcultures. In developing model personalities for different societies, one assumes that the typologies of character can be statistically measured.

The fourth perspective, normality as process, stresses that normal behavior is the end result of interacting systems. According to this perspective, temporal changes are essential to a complete definition of normality. In other words, the normality as process perspective stresses changes or processes rather than cross- sectional definitions of normality.

Investigators who subscribe to this approach can be found in all the behavioral and social sciences. Most typical are Grinker's thesis of a unified theory of behavior encompassing polarities within a wide range of integration and Erikson's conceptionalization of the seven developmental stages that are essential for mature adult functioning. The recent interest in general system theory (Von Bertalanffy Gray, Duhl, and Rizzo) further stressed the general applicability of general system research for psychiatry. Normality as a system has been recently outlined by Grinker; variables from the biological, psychological, and social fields all contribute to the functioning of a viable system over time. The integration of the variables into the system and the loading (or significance) assigned to each variable will have to be more thoroughly explored in the future.

Illustrative Research Strategies

Studies on normal population have to a large extent concentrated on normality as health and normality as utopia perspectives. The epidemiological studies of Srole focused on disturbed signs and symptoms that interfered with the person's functioning and behavior. Leighton and his colleagues concentrated on gross psychopathology. On the other hand, studies of superior or very competent individuals have been undertaken by Silber, *et al.,* White, Cox, Heath, Westley and Epstein. There have been very few clinical or longitudinal studies illustrating the normality as average or

normality as process perspectives. In the section below we have chosen two research strategies that illustrate the usefulness of the latter two perspectives in empirical studies of normality and health.

Normality as Average—The Modal Adolescent Project

The overall aim of the Modal Adolescent Project has been to study intensively and over a long period of time one representative group of "typical," "average," or "normal" adolescents. A modal student was defined as one whose performance on a specially constructed Self-Image Questionnaire (Offer and Diesenhaus) was within one standard deviation from the mean in nine out of ten scales. As such it was our aim to study one population of average students by eliminating both extremes; the disturbed adolescent as well as the teenager who functions on a superior level. Since the above study was undertaken in two suburbs of Chicago, the adolescents represent average middle-class suburban teenagers. Data were collected in order to provide a base line for comparative data collected on other populations both in our culture and cross-culturally as well as in future generations. It will become part of a data pool that will give scientists a better understanding concerning the totality of the phenomena of adolescence.

At the onset of our project we wanted to select our modal group from the widest possible spectrum of teenagers living in a particular community, so

a natural choice was a high school attended by all teenagers in the community. We chose two different high schools that were limited to middle-class populations but, nevertheless, represented the full range of the middle class. For our selection procedure we devised a Self-Image Questionnaire that we administered to the two total entering freshmen classes. "Normal" or modal subjects were chosen on the basis of a statistical approach, normality as average. This method was selected in order to attempt to eliminate the extremes of psychopathology and of superior adjustment.

Our research strategy helped us understand the kind of problems typical teenagers have, the way they cope with them, and the reasons behind their successes and failures in the coping process. Our findings are summarized below:

1. There was a history of almost complete absence of gross psychopathology or severe physical illness.

2. There was a history of mastery of previous developmental tasks without serious setbacks.

3. Our subjects demonstrated ability to experience affects flexibly and actively bring their conflicts to a reasonable resolution. In general, our subjects coped well with anxiety, depression, shame, guilt, and anger.

4. Our subjects had relatively good peer relationships as well as a capacity to relate to and identify with adults. During high

school the father is seen as reliable and the mother as understanding. The adolescents feel closer emotionally to the mother. After high school the subject gets closer emotionally to the father.

5. Twenty-two percent of our subjects experimented with delinquency between the ages of 12 and 14. They had a capacity to learn from their experiences and did not become chronic delinquents. During high school they handled their aggressive impulses mainly by channeling them into sports. After high school and particularly during the first year away from home, we noted some mild depression among our subjects.

6. There was evidence of discomfort but no marked conflict with the increasing strength of the sexual impulses. Our subject moves slowly in the direction of heterosexuality. There is no evidence of a "sexual revolution" in behavior among our subjects. Nevertheless, in their attitudes they seem open and willing to discuss sex.

7. There was no evidence for the existence of serious "adolescent turmoil." The lack of serious "adolescent turmoil" was not a reflection of denial or closed off communication with the self. Indeed, introspection was prominent and communication with the self is present. The adolescents show some awareness of conflicts with parents and authority figures, but the conflicts do not spin out of control. They have surprisingly realistic self-images and are actively bringing their conflicts to a successful resolution.

8. There was a great deal of continuity between their values, those of their parents, and those of the social milieu of their community.

We discussed our findings concerning one group of normal or typical teenagers in detail to illustrate how such a research strategy can be useful. It tells us how a specific group of adolescents feels and behaves. It serves to establish the beginning of behavioral norms for one group of adolescents; thus when future groups of teenagers are studied, especially from the same sociocultural backgrounds, they can be meaningfully compared with the group described above.

Similar studies on modal populations have to be performed on a variety of populations throughout the life cycle in order for us to have a better understanding of the factors that contribute to adaptation and health as well as those that contribute to the development of psychopathology and maladaptation.

Normality as Process—Parental Anticipatory Mourning

In the previous discussion we have indicated that a process conception of normality involves an investigation of multiple systems of adaptation transacting over a period of time. In contrast to cross-sectional perspectives, a process analysis emphasizes temporal progression of coping techniques and

assumes the continuity of change in behavioral patterns. While this particular perspective has been espoused by many mental health professionals on a verbal level, the empirical evidence supporting this understanding has been less convincing in the behavioral sciences than in several of the biological sciences (for example, embryology and evolutionary theory). In part the understanding has been hampered by a lack of empirical data so that the discussions of the process perspective have often appeared to be abstruse and divorced from concrete behavior. Consequently we have selected a particular research program to illustrate a more comprehensible picture of normality as process. The illustration is intended to summarize the formulation of a process analysis derived from empirical data in a longitudinal study.

The particular work that we have selected as an illustrative paradigm for normality as process is the work during the past five years by Futterman, Hoffman, and their colleagues in the area of family adaptation to the fatal illness of a child. In this study each of the four perspectives is utilized to a certain degree. However, the overriding interest of the investigators is in studying coping behavior over time. The specific interactions of the various defensive structures (or subsystems) and their contributions to cluster behavior arc being investigated. Their method is similar to the one utilized by Vaillant in his 30-year follow-up study of healthy adults. The central question is what were the contributing factors that helped bring about successful

adaptation.

These investigators have studied the coping mechanisms of parents with leukemic children. They have interviewed and observed a normative sample of parents and their children from the initial communication about the fatal illness up to, and in some cases following, the death of the child. To carry on such studies is in itself a most formidable task considering its extreme poignancy. Indeed, recent work by Paykel has indicated that the death of a child is considered to be the most upsetting event conceivable to an adult population of psychiatric patients and their families. Nevertheless, several research teams (Friedman, *et al.,*Richmond and Waisman, Bozeman, *et al.,* Natterson and Knudson, Hamovitch, Binger, *et al.,)*have carried on investigations in this area with the realization that much can be learned by studies of a normative population undergoing stress of high intensity over a substantial period of time.

Futterman and Hoffman conducted formal interview's with 24 sets of parents supplemented by informal contacts with many other families, in collaboration with the Department of Pediatrics at the University of Illinois. From the very beginning the observers were impressed with the wide repertoire of coping strategies utilized by the involved families. While the exact criteria for successful coping with this dreadful stress remain to be worked out, the research team has focused upon the modal processes of

adaptation in their sample. Examination of the data after two and a half years of observations indicated that each set of parents had to cope with the following adaptational dilemmas:

1. To trust the caregivers (physicians, *et al.)* and yet to accept their limitations.

2. To be active in mastery of the chronic stress and yet to delegate appropriately to the caretakers.

3. To acknowledge helplessness periodically and yet to maintain their own sense of worth.

4. To cherish and cling to the leukemic child and yet to allow the child to separate from them and continue to grow.

5. To invest in the leukemic child and yet to invest also in the child's siblings.

6. To accept medical reality and yet to maintain a certain amount of hope.

7. To develop acceptable outlets for anger and yet to avoid excessive bitterness at others or persistent self-blame.

8. To mourn the impending loss and yet to maintain investment in the child's further development until death becomes imminent.

9. To focus on the immediate crises and yet to plan for the future of the family.

10. To protect significant others (relatives, friends, teachers) from too great a stress and yet to prepare them also for the child's death.

11. To maintain strategies of continued existence and yet face feelings of hopelessness, helplessness, and grief.

After analyzing these dilemmas the investigators further postulated the following interdependent five areas as major adaptational tasks of parents with leukemic children:

1. Maintaining family integrity.

2. Maintaining confidence (worth, mastery, trust) in themselves and the child's physicians.

3. Maintaining meaningful value orientations (for example, causality, meaning of life and death, hope, and so forth).

4. Managing their awareness process and feeling states.

5. Anticipatory mourning.

Each of the above adaptational tasks was further analyzed into its various components, and efforts were made to follow these adaptational subtasks throughout the course of the child's illness and even beyond the death of the child.

The concept of parental anticipatory mourning was developed

empirically from the data as a series of adaptive part-processes interwoven throughout the trajectory of the illness (Futterman, Hoffman, and Sabshin). Preliminary inspection of the data showed that certain components emerged and reached prominence earlier in the child's illness while others peaked in the latter stages of the disease. The part-processes emerging from qualitative analysis of the data included the following:

1. Acknowledgment: development of explicit awareness (Glaser and Strauss) of the fatal prognosis; becoming convinced that the child's death is inevitable.

2. Grief and grieving: experiencing and expressing the emotional impact of the anticipated loss and the physical, psychological, and interpersonal turmoil associated with it.

3. Reconciliation: coming to terms with the child's expected death in a manner that preserves a sense of appreciation of the value of the child's life and of life generally.

4. Detachment: withdrawal of emotional investment from the child as a growing being with a real future.

5. Memorialization: development of a relatively fixed internal image of the child with investment in his memory replacing investment in the real child, occurring before the death of the child.

These phases were postulated after the data were examined

qualitatively; they are being checked currently by quantitative analysis to assess the frequency of their occurrence, their precise phase-specific relationships, and the various deviations from modal patterns. Several of these variables have been discussed by other investigators of parental adaptation to fatal childhood illness. However, other authors have not treated the course of parental anticipatory mourning as a total process, nor have they described the progression of each of its part-processes and their dynamic interactions over time. In addition, a number of specific constructs, among them "reconciliation" and "memorialization," are formally introduced by Futterman, *et al.*, for the first time as integral aspects of anticipatory mourning.

Parental anticipatory mourning is still a relatively unexplored field. In this chapter we do not wish to focus on it as a clearly defined entity; rather we wish to illustrate empirical research in which the processes of coping over time are studied in a sample of individuals who do not specifically seek psychiatric help. We envisage a variety of such longitudinal studies as helpful in elucidating processes of adaptation so that normality as process becomes much more understandable as a perspective complementing the others discussed in this chapter.

Coping and Adaptation

Normality and health have often been associated with terms such as adaptation, competence, and most recently coping. We have to keep in mind that these concepts, like normality and health, are complex theoretical constructs that have not been adequately explained on the basis of any past or present single theory or hypothesis. One of the major problems that has plagued investigators in the behavioral sciences has been the great difficulty in making successful predictions about the long-term future behavior of an individual, or even of a majority within a group. Current research endeavors in the behavioral sciences have, therefore, tended to identify operationally clusters of traits and behavior that describe the variety of healthy or normal populations. (See, for example, Silber, *et al.,* Grinker, *et al.,* White, Heath, West- ley and Epstein, Cox, Offer, Beiser, and Vaillant).

The interest of behavioral scientists in studies of coping and adaptation has increased rapidly in the past two decades. A variety of definitions of coping has been offered in the literature. Hamburg and Adams define coping as "seeking and utilizing of information under stressful conditions." Heath defines adaptation as "to so regulate behavior as to optimize simultaneously both the stability of the self structures and their accommodation to environmental requirements." Coping is defined by Lazarus, *et al.* as consisting of problem-solving efforts made by an individual when the demands he faces have a potential outcome of a high degree of relevance for his welfare (that is, a situation of great jeopardy or promise), and particularly

when these demands tax heavily his adaptive resources. Competence, according to White, means "fitness or ability. The competence of an organism means its fitness or ability to carry on those transactions with the environment which result in its maintaining itself, growing or flourishing."

Ability to cope is another way of assessing the type of character of the defenses utilized by individuals; the "healthier" the defenses the better the coping abilities. (See, for example, Grinker and Vaillant.) A recent review by Weinshel includes a discussion of the direct correlation between ego strength and health and normality. Here again the stronger (or healthier) the ego the easier it is for the individual to adapt to his internal as well as to his external environments.

From a physiological point of view studies of coping mechanisms tended to agree that: "It is not the stimulus that is specific but the response. Response specificity clearly is based on phenotypic patterns based on combinations of genic and experiential factors." Recognizing the importance of response specificity, the most significant investigations of coping behavior have involved analysis of variations in responses to stressful situations. The fact that a large variety of stimuli from either the external environment or the internal environment (for example, affects such as anxiety, anger, fear, or depression) all have a common physiological pathway has made it easier to study the somatic responses to stress. It has not, however, made it any easier

to study the coping behavior of people from a psychological point of view. The individualized response, which is based on constitutional, experiential, familial, social, and cultural factors, is not uniform. Hence the 20 universal stressful situations[1] outlined by Hamburg are coped with in a variety of ways rather than having a uniform pattern of "response specificity." Thus what causes one person to be unable to cope (for example, death of a close relative or friend) *at a particular time* will not necessarily cause the same response at a different developmental state. A knowledge of the individual's background can tell us what defense mechanism (or coping behavior) an individual will choose to combat a particular stress. However, psychiatrists have not been too successful in the past in predicting who will cope successfully under stressful conditions.

In the section on parental anticipatory mourning above, we have described a specific study that deals with one of the stressful situations outlined by Hamburg. The physiological system that has been activated by the parents in acute stages of grief is not intrinsically different from the system that the soldier activates in battle. The psychosocial response, however, is less specific. Hamburg and Adams state that there are basically four stages in relieving stress of major proportions: "1. Personality attributes that tend to facilitate involvement in and mastery of the new situation or task; 2. Ego processes that serve to develop an adequate self-image in regards to the new task or situation; 3. Ego processes that help to maintain otherwise distressful

affects within manageable limits; and 4. Personality processes that tend to maintain and/or restore significant inter-personal relationships."

The basic assumption still is that the royal route to studying psychosocial coping is through deviancy, be it psychopathology (Jones) or unusual (that is, stressful) situations or conditions (Hamburg and Adams, Grinker and Spiegel, and Lazarus).

To many investigators the term "coping" implies that there is something negative to which one has to attend. This view of coping is conceptually similar to the psychoanalytic theory of defense mechanisms—the defenses are erected to protect the person against the upsurge of powerful aggressive and sexual instinctual demands from within and to protect him from undue pressure from without. From this perspective the best way to study coping is by observing populations that are experiencing stressful reactions in highly conflictual situations.

Erikson presents human growth from the point of view of conflict, crisis, and stress: "For man, in order to remain psychologically alive, constantly resolves these conflicts just as his body increasingly combats the encroachment of physical deterioration" (p. 91). He postulates that during the eight specific crisis periods one can study the human condition better because both the potential for growth and the emergence of pathological defense

mechanisms are more evident. It remains unclear whether Erikson extends the crisis periods to include all substages or phases of the eight crisis periods. The concepts that delineate the beginning and end of each crisis period have not as yet been operationally defined. Erikson assumes that crisis, like stress, elicits emergency defenses; hence the study of crisis serves as 3 way to decipher how well a person is able to cope.

An alternative perspective to sequential life crises is one that assumes periods of relative equilibrium and disequilibrium. Tire modal adolescent described above goes through adolescence without reacting to it *in toto* as a stressful situation or even as a series of *major* crises. Coping can, therefore, be studied in this context by observing quantitatively different phenomena, for example, the most ordinary life situations of one group of teenagers. Adolescence is certainly not conflict-free, and the adolescent must disengage himself from parental domination. He can do this without total renunciation of parental values, but rather through conflicts or minor issues that have been endowed with major importance for the adolescent's own growth and development. At least in the modal adolescents the reactions do not give rise to the storm and stress described by investigators studying intensive experiences of adolescence and experiences such as combat conditions (for example, *Men under Stress).* To describe the adolescent period as a period of great inner turmoil, rebellion, storm and stress is true for a segment of the adolescent population, but is not universally observed. Like any period in life

it is highly stressful for some individuals. For the latter group their coping abilities are often inadequate, and hence they commonly seek help in the psychiatrists' offices. The adolescents who cope successfully with the period are an enigma to many clinicians. We need new terminology that will describe the nuances in coping behavior and that will take into account the tremendous variability in reactions of individuals to stress and crisis. It will allow us to view a continuum of stressful situations from most stressful to the least stressful, with crisis being at one end of the continuum and successful coping with everyday tasks at the other end.

Studies of adaptation and coping would enable us to formulate what Jahoda called "positive aspects of mental health." While psychiatrists have always been quick to extrapolate from psychopathology to normative theory, it has not been simple for psychiatrists to focus upon adaptive aspects of human behavior. Until very recently our theoretical concepts have facilitated the examination of nuances and details in studying psychopathology. In addition, psychiatrists are adept in perceiving coping behavior correctly, but still clothing it in the garments of psychopathology.[2] With the developing sophistication of ego psychology, it has become increasingly obvious that there is a need to investigate the correlation between the behavior and specific coping ability of people and their overall psychological health and normality.

Returning full circle now to our original question: What is normality and health? We believe that there are a number of adaptational routes open to individuals. Based on a complex interaction of biopsychosocial variables in a system that we call an individual, a person will have developed a coping style unique to him early in life. It is our opinion that in a majority of individuals the psychological system that an individual erects in order to cope with crisis, stress, and everyday life will by and large remain relatively constant through life, since the repertoire of adaptive mechanisms, including defenses, is relatively fixed in early childhood. Some individuals will undergo *Sturm und Drang* at every major crossroad through the life cycle. Others will go through life with little turmoil. We postulate that the healthier individuals will have a variety of coping techniques available to them, will have a larger array of defenses at their disposal, will utilize the more adaptive and object-seeking defenses, and will show more flexibility in dealing with internal as well as external events. Whether the ones who show less overt (behavioral) turmoil are the ones who are optimally healthier cannot be determined without intimate knowledge of the biopsychosocial variables that contribute to the behavior. In other words, behavior has to be studied in the context of the individual, the family, the group, and the society. Only then can it be fully understood.

It is imperative that we study the behavior, psychodynamics, and coping styles of a large segment of the population in order to understand the

contributing factors to adaptation or maladaptation. Recent trends in social and community psychiatry afford us some new opportunities to achieve part of this goal.

Social and Community Psychiatry

The issue of normality has already become a visible question in the development of social and community psychiatry. Although some investigators have clearly recognized that conceptual dilemmas regarding the definition of normality exist when one conducts epidemiological studies or attempts primary preventive programs (Mechanic and Bolman), the problem is rarely acknowledged. There is reason to expect, however, that a series of events will force even greater consideration by community mental workers of perspectives of normality. Discrepancies in prevalence and incidence rates of psychiatric illness across subcultural and geographic boundaries are determined, at least in part, by variations in the operational definitions of normality or health. Furthermore, efforts at evaluation of preventive programs (primary as well as secondary prevention) must include criteria for successful as well as negative outcomes. Comparative analysis of such results in community mental health programs across the nation will necessitate consideration of the operational definitions of illness and health, and there will be increasing pressures to improve upon our gross definitions of psychopathology and healthy adaptation.

There is another reason why normality will emerge as a central research and pragmatic issue in social and community psychiatry. The development of community mental health programs affords an excellent opportunity to begin a series of investigations of normative behavior not heretofore possible. Although the image of communities as laboratories for research has brought about resistance as well as consternation in some areas, there is reason to believe that the efforts to conduct investigations *with* communities will, after some hesitation, supplant our tendency to do research *on* communities. Evidence already exists indicating the advantage to communities of increased understanding of its population's behavior as compared to stereotyping and its attendant distortions. Furthermore, communities will be interested in evaluation of intervention programs within their borders, and they will cooperate with investigations that facilitate such evaluation.

One of the best illustrations of *access* to a normative sample and community *sanction* for research in the area of psychological adaptation and maladaptation has been the pioneering investigations by Kellam and Schiff. They have demonstrated the feasibility of such studies and have also contributed significantly to our understanding of behavior in a large sample of schoolchildren. It is to be hoped that over time many more populations will be investigated so that our empirical evidence will be considerably augmented.

Summary

Concepts of health and normality are not universal or all-encompassing. They tend to reflect the particular orientation or values of the investigator and are often tied to the social context in which the research is undertaken. We have described four major perspectives on normality: normality as health, normality as utopia, normality as average, and normality as process. We further described two research strategies that can be seen as illustrating two of the four perspectives on normality.

The trend toward increased study of normative population by mental health professionals can be well documented in a variety of other mental health areas. It is important to note that convergences have already begun to take place, as, for example, in the convergence of community psychiatric studies and human development within an epidemiological framework. We have seen in the past decade a dramatic increase in investigators studying the factors contributing to coping under stress, as well as the psychological processes relative to successful adaptation in everyday life. Many more studies will be necessary before a useful integration of the concepts of healthy adaptation, coping, and normality will be possible.

Chapter 9

The Concept of Psychological Maturity

Rachel Dunaway Cox

The Meaning of Maturity

Since the early 1950's maturity as a term and a concept has come into widespread use in psychiatry, psychology, social work, and education. Its facile employment in both formal presentations and informal discussions might suggest that the parameters of maturity have been systematically, unambiguously established. Actually this is by no means the case; although the state of maturity, often assumed to be synonymous with psychological health, is described in a growing body of literature, the number of empirical studies is still relatively small.

Psychological maturity is, in fact, a difficult subject for scientific inquiry and scholarly discourse. The hazard in treating it stems in no small measure from the tacit assumption that everybody—professional and lay people alike —knows what is meant by the term. The seeming general agreement about

meaning may well arise out of the vagueness of the concept itself and the looseness of the way it is discussed. The inexactness and hence the slipperiness of the ideas clustering around psychological maturity is no doubt characteristic of any emerging concept and its lexicon, which will in time give way to greater precision. Meanwhile, the usefulness of the notion of psychological maturity is matched, perhaps exceeded, by its opposite—immaturity. Both concepts have come into rapid currency because they seem to describe aptly an important unitary something about persons. The great serviceability of the idea and the terminology has thus led to an accretion of meaning that makes for a certain level of communication. Indeed, maturity has become an allpurpose word, vague enough to fit into any context where a desirable, healthy, balanced commendable state is implied. Helen Lynd perceptively points out an unacknowledged but implicit meaning that the term has come to carry—a meaning that nonjudgmental professionals would probably disclaim in referring to attitudes and behavior. The words "good" and "bad," she says, "have been replaced by mature and immature, productive and unproductive, socially adjusted and maladjusted. And when these words are used by the teacher, counselor or therapist they carry the same weight of approbation and disapprobation as the earlier good and bad," and constitute a code as specific as that they have replaced. If she is right, certain moral overtones have crept unbidden into estimates of maturity and immaturity.

In the field of education the concept is also found serviceable.

Unhappily, teachers sometimes resort to the term "immature" when they either feel it is inadvisable to tell parents the hard truth or are themselves very unclear about what ails a failing or near failing pupil. In this situation confusion rather than understanding is communicated. Only one thing is certain when a teacher tells a parent her child is immature. This is that the teacher regards the child as unsatisfactory. In what ways and to what degree and with what hope of change for the better are often obscure to teacher and parent alike.

A frontal approach by research on psychological maturity or, to use the interchangeable name, psychological health has been long delayed. Preoccupied with pathology, psychiatry has until quite recently directed its attention away from health. Committed to precision of methodology and narrowly defined variables, academic psychology has explored isolated bands of behavior in experimental settings or limited itself to infinitely detailed and thorough descriptions of child growth. The Early Childhood Education movement, borrowing freely from both psychoanalysis and academic child psychology, has historically reached a more profound understanding than any other branch of psychology of how body, intellect, emotion, and social interaction meet and fuse with environmental opportunity to produce successive levels of maturity. In their close association with young children developing at a very rapid pace, nursery school teachers long ago saw that growth must be understood as a holistic phenomenon, indivisible into its

separate components. Important and perceptive as its work has been, Early Childhood Education has remained for the most part a self-contained applied field. So-called basic research and theory building has been on the whole left to other branches of the discipline.

Thus for a variety of reasons the systematic exploration of the concept and status now known as psychological maturity has only fairly recently become a topic to be researched. Heath who has produced one of the more thorough studies, acknowledges that the construct "maturity" has been criticized by psychologists impatient with inexact and subjective evaluations. He insists, however, that the results of his research on college men show *how*persons subjectively judged mature differ from those judged immature. In fact, the findings, not only of Heath but also of the body of empirical research on psychological maturity —scant though that research is—are in substantial agreement about the manifest traits and behavior of the so-called psychologically healthy person. This general unanimity points toward what Heath calls an underlying psychological reality.

Even while the loose and sometimes confused use of the terminology of maturity has gained momentum, research, theory, and expository discussion have produced a stimulating and significant, if numerically limited, literature. Many streams of thought mingle in present-day conceptualizations of psychological maturity. Contributions from the mental measurement

movement, from the psychology of cognition, from sociology, anthropology, and social psychology, from both psychoanalytic and academic personality theory can be discerned in most scholarly and workaday references to the idea and the terminology. The significant point is that in its present use psychological maturity is a concept relatively new to science. While it unquestionably has a legacy from moral philosophy and religion, that rigor is softened by known facts about how development is rooted in genetic potential interacting with environmental offerings sometimes generous, sometimes niggardly. The concept includes the idea that physical soundness supports the totality of growth, but does not accept the notion that poor health forecloses the possibility of mature personality. The quality has been studied almost exclusively by using subjects who are intellectually well endowed, highly educated, and well above the poverty line economically; but the certainty remains in the minds of expert and laity alike that many individuals only moderately bright, poorly educated, and in the lower ranges of income actually do acquit themselves exceedingly well.

What, then, is psychological maturity? A consensus of experts on human behavior coincides reasonably well with the popular use of the term. This holds that mature persons are clearly aware of reality and that they do not run head on to violate it, though they do what they can to shape it to positive ends. Reaching out in trust and warmth to other persons, they are able to give and accept affiliation. Being essentially at peace with themselves, they are

attentive to the needs, joys, and griefs of others. Enjoying productivity, they work in accordance with their gifts and tend to grow steadily toward higher levels of competence. These characteristics are attainable at any time of life by individuals of any status. They constitute what might be called the invariants of maturity.

It may be that the aptitude to achieve the somatic, psychic, social unity required has a genetic core. This is a question as yet scarcely formulated. It cannot be denied that good intellect, a basic minimum of economic wellbeing, social and vocational opportunity that protects against intolerable frustration, and, most critically, good physical health are circumstances most often associated with psychological maturity in researched groups. Yet the possibility of an overall effective level of being that satisfies the criteria of the reality-oriented, productive, and loving way of life is achieved by persons who have relatively little to work with. How such individuals cope with their situations, preserve their intactness as persons, and keep to a steady course is a research area as yet wholly unexplored. Locating and getting the cooperation of subjects and the choice of feasible methodology present problems so formidable that the hurdles in work with the highly endowed are child's play by comparison. Nevertheless, it is to be hoped that qualified investigators will make the attempt. Meanwhile, the overview of the field undertaken in this chapter must perforce deal with the research and discussion now available.

Work dealing specifically with psychological maturity has concentrated almost exclusively upon adult subjects, most of them in their twenties and thirties when full biological and social maturation has presumably been attained. Important early work was carried on by Murray and by a group under medical auspices at Harvard (Hooton, Heath) before World War II. The years following the war brought a succession of studies (Barron, Bond, Brown Cox Sanford Terman), all of them beamed upon the adult years. On exploring what was essentially uncharted territory, these investigations had to adapt old or invent new methodologies that the individual researcher believed would produce relevant data. As publication dates show, much of this work was carried on simultaneously, each project having slightly different if similar aims and its own theoretical basis. As a result most of these investigations seem to begin *de novo.* It is captious to complain that studies did not at this early stage build one upon another. Timing and differences in research situations and resources as well as various aims made replication either impossible or inadvisable. The more significant fact is that work independently pursued and from different starting points came out with pictures of the psychologically healthy young adult that are in essential agreement from study to study. Furthermore, though the findings of the empirical work have given added dimension to the description of personality at its healthiest proposed by theorists and clinicians, they rarely contradicted it. Longitudinal studies did reveal some surprises. This had to do with the

severity of the stresses encountered by presumably mature young subjects in their later experience. Some of the stresses were environmental and could be said to be of the "act of God" variety. Others were psychological and developed out of conflicts and pain unique to the individual's psychic organization. Nevertheless, one of the most consistently appearing trends in the psychologically mature subject was the ability to recover from stress. Faced with disappointment or loss or disillusion that shakes him profoundly, he regains his equilibrium as if by some inner "righting mechanism" and resumes his course. (Note especially Barron, Cox, and Heath).

The steps by which the "righting" comes about are of particular interest. Cox, for example, found that continuing in an accepted role was supportive as was the less tangible framework implicit in a self-ideal. Ruff's work with the astronauts revealed that their command of specific skills that gave them a range of appropriate ideas of what steps might correct a system failure enabled them to control anxiety in space flights.

From all the in-depth research on criterion groups comes evidence that mature people are sensitively aware of the persons and events around them and recognize and accept the claim of others upon them. The mature individual is usually in harmony with people and with the basic institutions of his society; but if his own value system and his own clear sense of what he is and what he wants to become run counter to the ideas and events he

confronts in persons or in society, this tranquility may be disturbed but not fatally disrupted. His work, as expected, is well suited to his capabilities and is pursued with satisfaction to himself and for the enrichment of his society.

The strong and resilient people who have been subjects are given various descriptive names or descriptive phrases by the investigators who studied them. They appear in the literature as self-actualizing, sound, psychologically healthy, or normal more often than as specifically mature. The different titles or names appear to carry essentially the same content and will be treated here as bearing on the same psychological phenomenon. In actual fact the subjects of this particular part of the literature have been biologically and socially adult.

Although the major research efforts have not denied the possibility that there is such a thing as psychological maturity before and after the blossoming of the early adult years, they have either not entertained the idea or have given it only passing mention. However, the present-day widespread use of the term and the idea of mature and immature levels of development in the growing years make imperative the recognition that there is not one but many levels of maturity—each appropriate to particular points in the life cycle.

Long before specific studies of psychological maturity under various

labels began to appear, research in developmental psychology had produced a vast body of information about infants and young and school age children who were functioning in accord with their good potential. Terman and Hollingworth, Witty and others studied gifted youngsters and revealed a complex of desirable personality traits as well as excellent physical endowment accompanying remarkable intellectual gifts. These researches did not set out to delineate psychological maturity as an entity in the latency years, but one of the significant by-products was just that. Contrary to belief current at the time that highly intelligent individuals were physically puny, socially withdrawn, and emotionally unstable, the gifted children were found as a group to be superior in every way, enjoying robust health, well-coordinated physically, socially well-adjusted and acceptable to their peers. Their behavior and personal qualities would seem to be precursors of the modes that much more recent research has found in adults who meet criteria of being notably well- functioning persons.

In numerous intensive cross-sectional and longitudinal studies of children appear evidences of individuals whose level of behavior reflects unusual capability in dealing with the experiences of their time of life. Retrospectively it seems clear that these children were working and loving in a way appropriately sensitive, complex, and effective as well as intellectually appropriate for their chronological age. Follow-up studies found them after infancy and earliest childhood maintaining not only their high I.Q.'s but, more

significantly, their competent way of life. These findings suggest that psychic maturity can be validly viewed as a process, a continuously evolving state that can be attained early in life but that moves unceasingly toward later revisions as changing tasks and circumstances require. I shall have more to say presently of the concept of the norm from which this idea of psychological maturity derives.

Over the last four or five decades two threads of psychological investigation, following different theoretical paths and employing entirely different methodology, have simultaneously made important contributions to the concept of maturity. On the one hand, psychoanalysis, and the elaboration of its theory in ego psychology, has traced affective and intellectual growth toward full stature. On the other hand, more recently the psychology of cognition in children has become a powerful influence on the way maturity is conceptualized. Its single most significant thrust has been its explication of the orderly progress of the genetically rich but cognitively naive infant toward the extraordinary complexity of abstract thought in the adolescent. These two approaches to the maturation process have been, and in large measure remain, separate despite the urgent need on the part of psychiatry, psychology, and education for a synthesis. Such a synthesis is by no means in the immediate offing, but the theories, empirical investigation, and expository statements of the analytic and the cognitive approaches seem to be moving together into much greater harmony.

Leading the way for psychoanalysis, Hartman, as early as 1939, declared for an autonomous ego, active in "conflict-free" spheres of memory, imagination, and maturity. "I think," he wrote again in 1964, "we have the right to assume that there are, in man, inborn apparatuses which I have called primary autonomy, and that these primary autonomous apparatuses of the ego and their maturation constitute one foundation of the relation to reality. Among these factors originating in the hereditary core of the ego, there are those which serve postponement of discharge, that is, which are of an inhibitory nature." He goes on to say that although the inhibitory functions derive from the conflicts between the ego and id, not all ego activities are devoted to such struggles. The ego is able to achieve on its own strength and to secure those achievements against reversibility.

The significant difference made in analytic theory by the postulation of an autonomous ego has only gradually been realized in the precincts of educational and descriptive child psychology where for so long psychoanalysis has been either rejected or disregarded. The revision, nevertheless, makes an incalculable difference in the acceptability of analytic theory in those circles and may eventually make synthesis possible. It is, however, Erik Erikson's particular interpretation of psychoanalysis that has created a climate in which nonanalytic physicians, teachers, and academic child psychologists can approach the theory with lessened wariness. Erikson accepts the psychosexual stages of historical psychoanalysis and traces

progress from the orality of infancy to full genitality at the dawn of adult life. When the individual falters on one step in the process, all that follows is in some degree compromised. The developmental sequence by which the ego eventually is able to deal effectively with the id and superego, and at the same time attain mastery of relevant actualities of existence, constitutes, he says, the history of maturation. Implicit in Erikson's view is the possibility of personal growth that can match the exigencies of unfolding experience, moving ahead unceasingly through early, middle, and declining years. He sees polarities of achievement and failure in succeeding epochs of the individual life cycle. These polarities state the central problem whose solution at each particular stage is necessary for the continuing development and health.

The polarity of basic trust versus basic mistrust in the early months of life is followed by autonomy versus shame and doubt in early childhood. In turn, the polarities of industry versus inferiority, identity versus diffusion, intimacy versus isolation, generativity versus stagnation lead on to the final stage in advanced age of integrity versus despair. Recognizing learning as related to these steps in growth, and weaving into his theoretical fabric a consideration of social identity, Erikson speaks with a persuasive voice to many schools of thought and has done much to lower the barriers that have so long compartmentalized descriptive, experimental, and learning psychology from the psychoanalytic and clinical. The massive resurgence in the last decade of the experimental impulse in child psychology and the rise

of the conditioning therapies take the science in a direction that seems for the moment to negate the rapprochement of recent years. Yet neither experimental nor neo-Pavlovian work has remained immune to what Erikson and like-minded psychologists have been doing. The new research differs markedly from the laboratory work with infants and children before the publications of Ribble, Goldfarb, and Provence, among many others.

Maturity of Cognitive Processes

The contributions of the psychology of cognition to the concept of psychological maturity are of a different order. Beginning in the early 1950s research and theory building directed toward the discovery of ways of knowing in infancy, childhood, and adolescence took a vigorous leap forward in America. This was due in large part to the impact of the work of Jean Piaget. [1] His prolific publications have continued to appear in a steady stream since the late 1920's, when his interest was first aroused by the ways in which children's comprehension of the world differs from the adult mode. He pointed out—and his observations and researches over half a century support his conclusion—that many fundamental ways of thinking usually assumed to be part of inborn human equipment are actually the upshot of maturation, of discovery and learning on the part of the infant and young child.[2] Equally important for both theory and practical affairs is his demonstration that cognitive mastery awaits both the biological maturation

coming with the passage of time and the assimilation of experiences made accessible to the developing organism by its own maturing structures and the offerings from the environment.

The somewhat cool reception accorded Piaget's early work in the United States seems to have been due to his overreliance upon verbal responses from child subjects whose ideation, American psychologists believed, was far more sophisticated than their language could express. Piaget himself now concedes the point. The further fact that most of his work was available only in French limited his hearing in America. His later studies, now translated, on his own three young children and his ingenious experiments with larger groups of different ages have aroused enormous enthusiasm here, as elsewhere, and stirred a growing company of psychologists to replicate and extend his approach and methods. In general, his ideas about the stages of cognitive development have been supported by investigations in Europe and America (Elkind, Smedslund, Wohlwill). These stages will be described in more detail later in this chapter.

He describes the development of intellect as taking place through the processes of assimilating experience and accommodating the existing structures or schemata to the unfamiliar information. This, in turn, creates increased readiness for assimilating new incoming experience and the elaboration of schemata to the new state of affairs.

This formulation actually constitutes a fresh statement of the vexing nature-nurture problem that reached stalemate some 30 years ago. As such it speaks with particular relevance to whole societies as well as to professionals concerned with maximizing human potential. In this context maturation is seen as an open- ended proposition dependent neither wholly upon genetic constitution nor upon socially proffered nurture, but upon some as yet loosely defined, dynamic interweaving of their respective contributions. Concurrent evidence from animal laboratories showing how early deprivation stunts and distorts a wide variety of growth patterns has provided an extension of data from the experimental sector.

The importance of Piaget's work for therapy, teaching, and social policy can scarcely be overstated. There are, of course, levels of deficit that no amount of skill in the helping process or enrichment of nurturance can overcome, but the necessity of continual provision of stimulation, highlighted by Piaget's work, as a requisite to further growth provides solid theoretical foundation for invigorated social and individual efforts on behalf of the socially deprived as well as the meagerly endowed. His work has also given additional urgency to social planning for early childhood since he stresses that later abstract levels of thinking rest upon foundations of schemata developed in early successive stages of growth. The critical importance of the capacity for abstract thought in developing a citizenry capable of democratic self-government is not actually stressed by Piaget, but it is of vital concern to

American educators and is likely to be influential in shaping teacher education in the last quarter of the century.

Although firm in his view that the sequence of steps in intellectual maturation is invariant, Piaget is less positive about what happens in the long run when there is a time lag in attaining any given level of growth. He surmises, however, that there is an optimal rate of progress from stage to stage. If the organism is delayed in a new phase, the ability to achieve the next level organization of experience may be unfavorably affected since the "new organizations cannot be indefinitely postponed . . . since they would lose their power of internal combination."

Piaget is, of course, concerned with the theory of cognition, but the principles and the stages he delineates also have applicability to treatment situations. The capacity to think, transpose, understand, and generalize can be, and indeed are, fruitfully adapted to the affective sphere. Thinking abstractly is supportive of the reorganization not only of cognition but also of behavior and emotion. The almost universal reluctance to make psychotherapy available to mentally retarded individuals has some justification in the fact that such patients, being handicapped in abstract thought, make little progress in the usual type of psychotherapy.[3]

A concern, which Piaget sees as typically American, with whether

intellectual maturation might be accelerated in extremely bright children by "forced feeding" appears to him ill- considered, and he sounds a warning on what the upper limit of expectation had better be.

A review of the range of work on psychological maturity reveals that the cognitive factor is a critical issue. As Heath points out, "A theme that weaves through most developmental theories is the centrality of man's maturing cognitive processes in assisting his adaptation." Both ego and cognitive psychology recognize this. The development by the two separate theoretical systems of the concept of stages— each resting upon that which goes before and laying the foundation of what is to follow—suggests that both schools of thought discern currents of growth that proceed along similar developmental paths. The fact that one system has addressed itself primarily to the affective sphere and the other to the cognitive makes the parallelism the more interesting.

As the foregoing discussion indicates, psychoanalytic, developmental, and clinical psychologies espouse quite similar assumptions about an interacting somatic, psychic, social indivisibility with predictable and stable sequences related in a general way to the sequences of life experience. Two other lines of investigation are of special importance to an understanding of the nature of maturity. The first of these is the concept of age-appropriate development. This idea has grown out of the mental measurement movement.

Originating early in the twentieth century, mental measurement now finds many of its assumptions taken for granted in lay as well as in professional thinking. Perhaps the most important of its working postulates is the use of the norm or central tendency as the reference point in evaluating performance and attitudes of many kinds. The second line of investigation derives from the self-psychology of academic personality theory.

The ideas, the methodology, and the extensive testing programs associated with mental measurement and normative research have always been strongly practical, even though important theories about the nature of ability based upon statistical manipulation of test scores have been a notable spin-off. Self-psychology, on the other hand, has been very largely theoretical and speculative, buttressed by both clinical experience and insight. The literatures of the two fields overlap chiefly where empirical studies of personality employ psychological tests. It is true also that the notion of the norm is implicit, even when unexpressed, in most evaluative approaches to living organisms. In the field of measurement the existence of an underlying integrating unity in persons, a major concern for self-psychology, is taken for granted. Ways to measure ego strength, which in many discussions seems to be used interchangeably with personal integration or self-stability, is of interest to theorists and clinicians alike. Personality inventories such as the MMPI and several of the projective techniques have been used by self, or ego, researchers sufficiently sophisticated in these methods to use them

effectively. (See especially Barron, Heath). It is probably not unduly pessimistic to say, however, that the clear delineation of norms for overall psychological maturity, and the measurement of self or ego strength, are still in the pioneering stage.

Age-Appropriate Maturity

Early in this century Alfred Binet developed the seemingly simple, but extraordinarily seminal, idea of age-appropriate mental development. Binet's very practical application to educational purposes of Cattel's earlier work on individual differences is based upon the recognition that a child's relative brightness must be judged by relating what he is able to do to his own chronological age, and that within broad limits his performance at any given age must be evaluated by comparing it with that of other children of the same life age. This device, later extended, with certain technical modifications by other workers, to adult subjects (Wechsler, and the testing programs of the armed services in World War I and World War II), has led to the elaboration of a vast and varied structure of norms in the form of quantitative statements of expectable, average performance on tests of scholastic aptitude and achievement, manual skills, attitudes and states of emotional health.

The age-appropriate idea leads at once to the proposition that the status called psychological maturity—that is, the ability to deal effectively and

resiliency with experience—cannot be conceptualized as a state achieved only in biological and sociological maturity, coextensive with the early and middle years of adult life. It is true, of course, that almost without exception the specific research on so-called psychological maturity has been done on adult subjects. This is probably so because intensive study of normal and supernormal persons has only fairly recently attracted research talent. It can be argued, nevertheless, that there are as many levels of psychological maturity as there are steps in the life cycle.

The point of view advanced in this chapter is that for each age span certain developmental tasks are implicit, and that psychological maturity is attained when these undertakings are accomplished in phase with chronological age and, in some degree of synchrony, with the expectations of the society of which the individual is a member. In infancy and childhood the rapid growth of the biological basis of the person increases and elaborates the requirements of age-appropriate maturity at dizzy speed. With every widening of the visual field, every extension of physical mobility, every proliferation of human contacts, every possibility for responding to social incitement, the complexity of required attainment increases. Thus, to maintain a once achieved relative level of psychological maturity, the individual must undertake continued revision.

At no time of life is static maturity possible since new situations demand

new adaptation. Furthermore, at certain critical junctures accelerated alterations of overt behavior and inner growth are required. Separation experiences occurring in new contexts at different points in the life cycle, the taking on of new roles and heavier responsibilities, the elaboration of human relationships as extension of the social network calls for increased subtlety and sensitive responses to hierarchies of loyalty— these and countless other passages change the constellation comprising mature feeling, thought, and action. Similarly in the decades following the middle years, receding physical resilience, the withdrawal in retirement of the social consensus concerning the individual's meaning and worth, and the loss of significant others make unprecedented demands.

As Scott has aptly said, "Maturation is more than ripening or growing older; it involves organization and differentiation as well." Of psychological maturity this is especially true. Equally true is the fact that only if reorganization proceeds unceasingly can equilibrium be maintained.

Psychological Maturity in Infancy and Childhood

To be in phase with appropriate overall maturation in the earliest days of life depends in major proportion upon sound biological equipment capable of advancing through normative processes of organic growth, myelination, and differentiation. This is not to say that individuals born with crippled

bodies or damaged nervous systems cannot possibly achieve integrated and effective lives. Evidence provided by occasional remarkable personalities shows that fully flowering personalities can develop in tragically damaged bodies. Nevertheless, very early somatic deviations, especially those involving the central nervous system, will slow and run great danger of permanently compromising healthy personality. Since manifestations of psychological adequacy in infancy are both experienced and expressed in somatic terms, being in phase with chronological age at that time of life depends upon soundness of body. This is especially true in the early stages of extrauterine life when the infant's grasp upon his world can be secured only by his contact with the space, sounds, touch, smells, and temperature of that world.

The interaction of the growing infant with his milieu in reaching toward comprehension of his world has been richly documented over the last hundred years by students of childhood as diverse as Darwin, Preyer, Shinn, Pratt, Carmichael, McGraw, Gesell, Bayley, Buhler, Escalona, Kessen, to name but a few from an innumerable list. The most favored approach to the study of maturation in the growing years has been the naturalistic or genetic one. Using longitudinal methods with fairly small groups, and cross-sectional approaches with much larger numbers, developmental psychology has minutely catalogued somatic structure, speech, ideation, social behavior, and the like from birth through adolescence. Norms of growth have been identified at closely spaced points along the continuum of chronological age

with a competence that will probably never be excelled. From the normative picture of different age levels, the characteristics and features of outstandingly effective functioning in the growing years can be spelled out.

As noted above, Jean Piaget has infused the genetic approach with new vitality. He cannot really be classified as concerned with norms in the usual sense, because his commitment to exploring the epistemology of cognition gives his work a theoretical and philosophic depth and breadth scarcely found in descriptive accounts of growth. Nevertheless, in setting out a sequence and in giving the steps approximate time boundaries, he does contribute to the notion of age-appropriate cognitive development.

The importance of the infancy and early childhood work for our understanding of the maturation of the total person can scarcely be overstated. From the earliest baby biographies down to the present, these researches throw into bold relief the basic interrelatedness of physical, emotional, and intellectual factors. Since World War II a series of studies have highlighted the blighting effect upon the growing organism where resources for wholesome growth are not available. The benchmark studies of Ribble and Spitz were followed by numerous investigations that sustained the early finding that infants deprived of ongoing contact with supportive emotional and social nurturance fall behind on all dimensions of development— including alimentation, neuromuscular coordination, cognitive and social

learning. The vehement critics of the Ribble and Spitz work have tended to fall silent as evidence has accumulated sustaining the central theses of their reports. The meticulously documented studies of Provence and Lipton demonstrate how lack of development merges into pathology—the marked opposite of a robustly normal state. More recently Rheingold has focused attention on the springs of language acquisition in the preverbal interchanges between the infant and his caretaker. Acting as a mother surrogate with a small group of institutionalized infants for a period of weeks, she offered them opportunities for vocal exchange such as mothers carry on with their own babies. Later evaluators, uninfluenced by knowledge of which infants had received social-vocal stimulation and which belonged to a control group, found the experimental infants notably more socially reactive and, indeed, somewhat more competent on baby tests than the controls. Rheingold's finding is in line with that of others who report that language acquisition is especially retarded by the absence of stimulation. Her experiment gives, however, the positive side of the coin in demonstrating that the introduction of preverbal stimulation makes a significant difference in the infant's own preverbal outreach.

Tracing the progress of age-appropriate affect has been the special province of psychoanalysis. According to that theory, the neonate is—and must be—an oral being, since to fail in the task of sucking, as some newborns with seriously impaired nervous systems do, is to incur grave hazard to life

itself. Rut as Erikson has pointed out, the infant takes in much more than physical nurture in this oral stage. He knows the world and interprets it in accordance with his oral experience. According to Erikson, the basic emotional achievement at this stage is the development of a belief in the readiness of his world to care about and for him. At three, or thereabouts, he will have come to terms with society's initial interference with his reflexive and instinctual life and begun to channel and control his intense loves and hatreds.

The ego of the psychologically mature child has gathered considerable strength by the time he is of school age. The conquest of his oedipal strivings has laid the foundations for identification and social feeling. His control of his own body, his command of information and skills, his growing awareness of the "rules" and expectations of society, as well as his capacity for satisfaction in knowing those rules and rising to those expectations, are impressive. At this point his faith in the world and his confidence in his own powers ready him for the further complications of life beyond the reach of his mother's arm.

Latency, as postulated by traditional psychoanalysis, is relatively free of the somatic and emotional struggle around sexuality, although Kinsey's retrospective reports on childhood showed that the years from six to twelve are by no means asexual and that interest in sex and sporadic sexual activity are neither perverse nor abnormally precocious. However, the most telling

indicator of psychological maturity at this stage is the style and energy with which the child gets on with the expansion of scope and skill in the ego apparatuses. Erik- son's depiction of the latency period as characterized, in emotional health, by industry speaks most congenially to developmental, social, and educational psychology. The industry that he proposes as the central enterprise of normal latency is expected to undertake school learning, to confirm a biologically suitable sexual identity, and to come to identify the self as a member of small and larger social groups. The opposed polarity, inferiority, is expressed in failure to achieve these goals. As teachers know, lag in the mastery of the various forms of symbolic learning does not merely constitute inconvenient deficits in the tools of school work. Such lacks are felt by the child and the society as deficits in the individual himself. The shock waves of these failures, reverberating into every aspect of the child's life, damage even the most tender social relationships, undermine self-esteem, and deteriorate self-image. This being so, it is inevitable that concern be keen that the young person "keep up" and remain close to suitably advanced school achievement.

Criteria of psychological maturity in middle childhood thus must include adequate progress in classroom learning. In deciding what is adequately "mature" in such matters for any child at a particular point in time, educators lean upon age and grade norms where these are available, as they are for most school subjects. The dangers inherent in the rigid use of

norm tables in dealing with individuals who differ markedly from the majority of schoolchildren in cultural nurture or personal idiosyncrasy is fortunately well known today. At the same time humane use of norms as guidelines for teaching, and occasional and judicious resort to them as a motivating force, can be helpful to both the child and his mentors. They serve to keep the realities of the child's school situation in view. School learning is, after all, a pressing reality for the child.

In the more subtle matter of becoming the sort of person the family, the school, and the society demand, landmarks are far more vague. There are no quantified norms for being an acceptable boy or girl, a normative son or daughter, a good team member. Although rarely spelled out, standards are nonetheless communicated constantly and are correctly understood by the latency child to be fairly unbending. He learns by apprenticeship, as it were, how to act and what roles to carry out. The histories of adults studied as notably mature reveal that these men and women were capable schoolchildren, not only successful in school learning but also in the varied and more inclusive roles and functions of their personal lives. There is little solid evidence on whether children who fail badly over an extended period in the tasks of latency can later achieve a high level of personal integration. We do know that adults who have been studied in criterion groups have not been failures in the past. Research on the psychological status of grown-ups who were earlier diagnosed as dyslexic or otherwise severely out of phase in

school learning might throw much needed light on the question.

Psychological Maturity at Adolescence

As childhood draws to a close, changes associated with puberty accelerate changes in psychological status. Intensifying demands of school curricula enforce decisions entailing long-range consequences. Educational choices made at this point are, happily, more reversible in the United States than in most societies, but even here the child must begin to think with a time perspective he has hardly known before. What he does—or more stringently, what he does not do—in his school tasks can be recouped only by unusual exertion. In his acceptance of these hard facts he expresses his developmental maturity. As to sex role, the individual has, of course, never had a choice, and awareness of his correct role has been emphasized since early childhood. In Western cultures, however, equalizing of opportunities and diversification in sociological roles has in the last half century tended to focus attention upon the samenesses in being human at the expense of attention to sex differences. With puberty, however, the female, especially, is confronted inescapably by the physical aspects of her femininity along with all its implications for emotional and sociological specialization. While physical maturation is less likely to be viewed as a mixed blessing by the young male, the sociological challenge to his male aggressiveness, toughness, and responsibility is formidable.

Both male and female must now relinquish old certainties and accustomed protections. Erikson describes adolescence as a period of natural uprootedness. Part of the maturation process is the questioning of values until now taken for granted. As this evaluation goes on the youth retires into his inmost self, questioning what he is really like and what he may become. This state of affairs is reflected in his Rorschach protocol, which now shows a decided swing toward introversion. This is surprising in view of the strong group orientation of teen-agers. But as Cox has pointed out, the teen-age clique serves as a kind of public relations agent for the adolescent while he, at his deepest levels, goes into executive session with himself. Meanwhile, observing the social scene, seeking clues about himself in the ways his fellows relate to him, trying out attitudes and roles in which he only half believes, he moves toward a revised individuality. So much is opening up for the adolescent that anything may seem possible to him. Fantasy and enthusiasm together with his newfound powers to entertain the hypothetical entice him at times beyond himself. The line between adolescent dreams and unreality may, even in the healthiest, sometimes become shadowy.

Erikson sees as the critical task the securing of the emerging identity against diffusion. In historical periods such as ours, rapid cultural change intensifies for all age groups beyond earliest childhood the problems of who one is and where he shall stand. For the adolescent whose self-revision is already creating so many inner uncertainties, the chaotic social scene

presents almost intolerable confusion about values, means, and ends. Emotional balance at this difficult time is best maintained, so clinical work indicates, by individuals who are able to preserve continuity with the past self while reorganizing and revising standards and goals in terms compatible with the realities of their present situation and with what the society beyond the family will expect of them and permit them to do and be.

With the upsurge of genital capacity young persons who have come through earlier phases of emotional growth and sex identification successfully now turn toward members of the opposite sex for recognition and confirmation of acceptability. The flowering of the capacity to love and to be loved by a sexually different being, and more especially to commit oneself unreservedly in trust to another, is the critical next step for the genitally mature. By the end of the adolescent years the emotionally mature man and woman are able to enter into faithfulness in love and the competence in work that can undergird the long-term relationship and the responsibility of nurturing a new generation.

Psychological Maturity in the Adult Years

Age-appropriate psychological maturity in the adult years has been more explicitly researched than that in any other period. The qualities of personality found in actual persons comprising criterion groups have been

set forth in psychological test terms and in verbal descriptions by a number of investigators (Barron, Bond, Brown Cox, Golden, Heath, Hooten, Sanford, Maslow). Informed reflections, growing out of clinical work, teaching and other human encounters, about the personality of the mature adult are found scattered through the literature of personality theory. (Note particularly Allport, Fromm, Lynd, Rogers, Schactel). The mature adult's qualities, as noted in the first section of this chapter, fully support Freud's surmise that in psychological health the individual would be able to love and to work.

Cox, taking functioning as an indicator of maturity, inquired into the adequacy of her subjects in the five spheres she deemed most important: preparation for vocational future, effectiveness in work, relationship to spouse and children, relationship to aging parents, and management of the practical realities of the home and money. Despite the generally effective functioning that this study revealed, her findings agree with Heath's that psychological maturity does not bring, even in these years of greatest emotional fulfillment, exemption from conflict and pain. The heightened awareness that their well-developed intellect and emotional comprehension bring, their openness to sensory impressions and intuitions, their essentially object-oriented approach in human relationships, and their sensitive involvement in the social issues of their time and place make them vulnerable. Their emotional health lies in their assimilation of these enriching experiences and their use of them to reach still higher levels of personality

organization.

The capacity to love deeply is not, as we have seen, reserved to the span beyond adolescence. But during the adult years it takes on greater depth and scope. The mature love experienced in lasting heterosexual commitments opens realms of feeling and action new even to those who have been able to love sincerely and securely in childhood and youth. Maslow found such relationships at their best to be singularly spontaneous, free of pretense and defensiveness, generously giving, seeking the comfort and enhancement of the beloved. Such a characterization is essentially that reported by the fairly limited number of other investigations that have inquired into the nature of love among adults in sound emotional health.[4]

Erikson, placing emphasis upon the production and care of a rising generation, gives to generativity the central role in emotional maturity of the adult years; and Saul sees the balance between receiving and giving to be more heavily weighted on the giving side.

Later Maturity and Old Age

The dimensions of psychological maturity in the last three decades of life have been explored very little by formal research. There is, of course, abundant evidence on the intellectual status of late adulthood and old age. In a long series of studies, beginning with the cross- sectional research of Jones

and Conrad and culminating in the standardization of the Wechsler-Bellevue Test of Adult Intelligence, the curve of growth from childhood to late adult life has been exhaustively documented. When the summed scores on standardized psychological tests are used to represent intellectual growth, the curve reaches its highest point in the early twenties, then enters upon a plateau that it maintains with relatively minor loss for two or three decades. Thereafter, the curve declines, reaching at length in the late sixties and early seventies the level attained by the average 14 year old. When the total score was analyzed and subtest scores scrutinized, it was found that the decline differs from one kind of ability to another. Verbal facility is maintained or increases right up to the onset of senility; tasks requiring completely new associations and those calling for rapid eye-hand coordination lose ground early and at a relatively rapid rate; abstract thinking, particularly as measured by dealings with spatial relations, occupies a middle range.

Later studies using longitudinal methods have thrown further, more optimistic light on the problem of aging. Intelligence tests repeated after 20 years on the same subjects did not yield falling scores. The earlier results seem to have been produced in part at least by an artifact of poorer schooling in older subjects. Yet when younger subjects today whose schooling is more recent and presumably more adequate are compared with older subjects, the young still outscore the older.

On the broader, more important, issue of emotional maturity unique to the closing years of life, there is very little solid evidence. Much is written and said about the unhappy plight of the very old—their loneliness, their sense of being forgotten, their sense of disintegration as persons because there are so few messages of reassurance from the non-self world. It is true that individuals selected as outstandingly mature in their earlier lives enjoyed then remarkably good physical health, generous recognition in their work, and satisfaction in their close love relationships. Does it follow that if and when these supports are withdrawn, as they inevitably are for most of the aging, there is no possibility for further growth or even for maintenance of already achieved levels of psychological maturity? Or is it reasonable to hope that in the presence of an intact central nervous system, the values, the manner of relationship, and the certainty of what matters, developed over a lifetime, can sustain and carry the individual onward to some hitherto unattained upland? Few psychological and social questions press so urgently for an answer. In this cause it is important that longitudinal studies already in progress be extended into the later lives of the criterion subjects.

Meanwhile, gerontology is discovering that not only in late maturity but also in advanced age, men and women can be restored and maintained in health by a vigor of physical activity once thought to be surely lethal.[5] The productivity of unusually endowed persons into their eighties suggests that continued work spurred by expectations on the part of the community

supports emotional health and, indeed, the totality of the person.[6]

Erikson believes that the later years offer the opportunity for the fully developed person to affirm the worthwhileness of the human enterprise and his own particular part in it. In rounding out this final phase of his growth, the individual may arrive at wisdom that maintains and conveys the integrity of experience despite the decline of bodily and mental functions. He concludes: "Potency, performance and adaptability decline, but if vigor of mind combines with the gift of responsible renunciation, some old people can envisage human problems in their entirety." Such old people can, he says, "represent to the coming generation a living example of the 'closure' of a style of life." Such acceptance and responsibility might well challenge human beings to further levels of maturity until the very end of life.

In sum then, the presence or absence in any individual of the quality of maturity is expressed by the way he bears himself in the tasks and roles of his particular time of life.

The Mature Self

The question of how an organism develops a style peculiarly its own, while keeping within the biological template of its species, continues to challenge science. Genetic endowment and the stage of physical and cognitive growth, together with the input from the environment, set limits. The level of

actual achieved maturity is, however, better conceived as the outcome of the ways in which these contributing components are marshaled in the service of the needs and purposes of the total organism. The synthesizing of resources, the selective responding, the directing of energy, and the harmonizing of many levels of thought and action in their totality are known as integration. The tendency or entity that makes integration possible appears to have its origins early in the life process. Since it unquestionably makes its appearance soon after birth and since its mode of relating to experience shows a certain consistency even then, it is surmised that this embryonic tendency toward a unique style may have an hereditary core. This entity, which becomes clearer cut and more individualized as experiences and the memories of them accumulate, is referred to by some theorists as the self. Others call it the ego. Although the terms are not synonymous, both designate a central, powerful aspect of human personality—its capacity to behave as a coherent unity over time, in a wide range of situations. A substantial portion of the theoretical and empirical literature on psychological maturity is devoted directly or indirectly to the nature of this unifier and undertakes to spell out its dimensions and the conditions of its development.

The present-day interest of academic psychology in the self represents a significant return to a topic that the science largely abandoned after 1890 or thereabouts. Some psychologists believe that the revitalized interest in the self is evidence of a maturing process in the science itself since the trend

means that there is in some quarters less disposition than formerly to treat as nonexistent an issue for which current conceptualizations and methods were inappropriate or inadequate. Historically, when psychology broke away from philosophy late in the nineteenth century, the notion of a unifier became increasingly uncongenial. William James suggested that there was no need for what might be called a supervising entity. For him the self was only the sum total of experience. "Each moment of consciousness," he said, "appropriates each previous moment and the knower is thus embedded in what is known. The thoughts themselves are the thinker" (Allport). A few psychologists resisted this view, insisting that a unifying principle held the parts together and was the overriding phenomenon (Allport), but they fought a losing battle. Uneasiness among the proponents of the new theory and methodology may have arisen, Allport surmises, out of their fear that psychology would excuse itself from its chosen tasks by assigning what was not readily understood in psychic behavior to "a mysterious central agency."

Psychoanalysis, however, going its separate way, never relinquished its interest in a unifier. Indeed, as Allport points out, "Freud played a leading, if unintentional, role in preserving the concept of ego from total obliteration throughout two generations of strenuous positivism" in psychological science. Freud's own ideas about the ego shifted over time and the concept has been further elaborated by Anna Freud. The ego psychologists, as indicated above, introduced into psychoanalytic theory important modifications, giving the

ego its own autonomy from the instinctual drive sources postulated by analytic theory.

Meanwhile, the turn of the wheel in academic psychology brought into being a point of view and a body of research that bears directly upon the idea and meaning of psychological maturity. This relatively recent development makes it possible to entertain the notion that there is such a psychic phenomenon as the self and to ask what a mature self is like. In his 1955 account of the renewed interest in the self by academic psychology, Allport said that many psychologists "had commenced to embrace what two decades ago would have been considered a heresy. They have reintroduced self and ego unashamedly and, as if to make up for lost time, have employed ancillary concepts, such as self image, self actualization, self affirmation, phenomenal ego, ego involvement, ego striving and many other hyphenated elaborations which to experimental positivists still have a slight flavor of scientific obscenity." A rising generation of psychologists has been less bound by the self- imposed restrictions of their predecessors and have been able to assert that an indispensable something was missing from the positivists' account of the human psyche. Whether the new work on the self takes theory beyond the point where the road forked in the nineteenth century remains to be seen. What is crucial, however, is that when some members of the psychological community turned away from the molecular approach, they returned to the field, as it were, and thus may be in a position to make progress in the

understanding of the self.

Relevant to our discussion of psychological maturity is the fact that in most treatments of maturity the idea of the self is recurrent. The notion that the psychologically healthy person has a solid sense of himself that he effortlessly affirms most of the time is substantiated by research and informed discussion. Like so many aspects of health, the robustness of the self is taken for granted unless it is belatedly or imperfectly established, or, having been partially developed, becomes unsteady. Then its keystone position in personality structure is unmistakable.

Of course, a unifying biological principle is operating in every living organism; but at the human level it masters extraordinary complexity, with the psyche not only maintaining its own consistency, capable of planning activities and developing values, but also standing apart from and regarding itself. It is symptomatic of the profound disturbance of the present era that uncertainty about the self is so widespread. It may well be, as Erikson has suggested, that uncertainty about identity is endemic in our time. On every hand are heard reports of young people who are vague and bewildered. They "do not know who they are" or what they are all about. The drug culture appears to be one of the malignant symptoms of the confusion. In the idiom of academic personality theory the unhappy state results from a poorly developed self. In psychoanalytic terms the egos of these individuals are

weak, brittle, shaky.

Psychological maturity, on the other hand, is characterized by a sense of inner cohesion that makes it unnecessary for the individual to question who he is. Except at natural choice points—as in career and mate selection—he is pretty clear about where he wants to go and about how his gifts are matched to the journey. Very early he develops a life style that he maintains over time, undertaking those inner revisions and those manipulations of milieu that enable him to realize his own potential and to use environmental givens fruitfully. In this vein Maslow describes self-actualizing persons. Fromm says that "the mature and productive individual derives his feeling of identity from the experience of himself as the agent who is one with his powers." Lecky insists that self-consistency is a necessary component of health. Heath, writing of the mature person whom he uses as coordinate with the term "mature self," finds him to be stably organized, able to resist disturbing information, well-integrated, allocentrie in his thought and feeling, and notably accurate in his self-image. Barron describes ego strength, a significant characteristic of the mature self, as a function of intelligence since, he says, the ability to comprehend experience, to store it in memory, and use it in positive ways depends upon the quality of the brain. He goes on to say, however, that intelligence alone does not account for ego strength. No less important are flexible controls that use repression selectively but at the same time keep the person "optimally open to experience." On the basis of his data

on personal soundness in a criterion group of graduate students, he concludes that within that population of subjects of ordinary physical and psychological integrity, soundness is by no means exclusively determined by circumstances but may be considered in the nature of an unintended—perhaps largely unconscious—personal achievement. Of his subjects, he said, "They are sound largely because they bear with their anxieties, hew to a stable course and maintain some sense of the ultimate worthwhileness of their lives." Through these descriptions of psychological maturity runs the thread of a clearly defined, well-maintained, purposive self moving toward judgmentally selected goals.

To recognize and even to describe the mature self is not the same as understanding it or divining its secret. Research on groups of mature persons gives an account of the nature of maturity and its antecedent circumstances: adequate intellect, stable childhood home, at least minimal economic provision, parents devoted to the child's welfare, educational and vocational opportunity. These favorable factors show high positive correlation with judgments of maturity in selfhood. Yet most of the studies also report that exceptional individuals become psychologically mature in the absence of one or several of these supports (Barron, Bond, Cox, Heath). Cox found that, in general, the more numerous the misfortunes and deprivations the greater the likelihood of loss of the personal equilibrium established at an earlier time. This agrees with the findings of the large sample study of Langner and

Michael, but Cox insists, as does Barron, that this trend is contravened in some subjects who grow to full stature despite difficulty.

Thus, the possibility that maturation may actually be accelerated and confirmed by felt difficulty is indicated by empirical research. Psychoanalysis long ago proposed that the ego grows through frustration and denial. Nagera, following the path laid out by Sigmund and Anna Freud, asserts that "some aspects of human development are due to frustration of primary needs of the newborn infant. Such frustrations," he adds, "are inevitable even in the presence of ideal conditions and ideal mothering." He adds that disturbance of the basic homeostatic equilibrium acts as a spur toward recovery of the equilibrium and concludes that "complete satisfaction would have made development from the original state unnecessary." This statement of the dynamics of ego growth recalls the growth of cognitive processes as Piaget outlines it. The development of cognition comes about when assimilation of new information demands accommodation of existing structures. This, in turn, facilitates the development of more complex schemata. The beneficent effects of stress are, of course, circumscribed by the capacity of the individual to absorb it, and if, as in the case of institutionalized infants, the deprivation is extreme, development is blocked.

Some years ago Claparede inquired where subjects felt the self to reside: in the right hand, in the viscera, in the center of the forehead, behind

the eyes, and so forth. This somewhat whimsical approach no longer engages psychology. The notion of body image, however, is influential in clinical practice and has inspired substantial research (Albee and Hamlin, Berman, Elkisch, Machover, Modell). Drawing of a person, whether designated as a self-portrait or simply as a man (or as a woman for female subjects), is believed to be an expression of the total self, with the inner sense of one's special strengths, weaknesses, and one's unique style expressed in line quality, relationship of parts to whole, size of drawing, and placement on the page. The self can, the clinician believes, be read from the body image expressed in the drawing. Whether this is true remains controversial, but there is enough supporting evidence to lead clinicians to use the drawings as one of several personality instruments.

Allport proposes what he calls the "proprium" to include all the regions of our life that we regard as peculiarly ours and reviews those aspects of personality that make for inward unity. In his eightfold schema of the proprium[7] he gives special priority to the bodily sense. The centrality of the body in psychological health is affirmed by all investigators. If psychological maturity is conceived—as we do here—to be expressed by the relationship between chronological age and psychic development, the bodily basis for the self is especially important. During the growing years rapid and continuous revisions of the body might be expected to challenge integration. Rarely, however, does healthy physical change disturb the self. On the contrary,

increasing strength and stature, improved neuromuscular control, the development of bodily skills, quite as much as the growth of cognition, extend and elaborate the infant self. During the latency years the self is supported and spelled out significantly in bodily terms.

In the beginning, as work with infants shows, the bodily self is learned. The way in which the young child discovers that the boundaries of his body have special relevance to all the rest of him and establishes his physical dimensions was vividly chronicled by Wilhelm Preyer in 1882. He recounted how his infant son learned by biting his fingers painfully that they belonged to the nearer parts of him. Later when the baby was standing in his crib, Preyer asked him to "give the shoe"—which lay on the crib beside the child. The little son complied. A moment later, Preyer, preparing to put the shoe on the child, requested, "Give me the foot." The child's response was to stoop and tug at his own foot in the same way he had reached for and lifted the shoe. At this point the knowledge that the foot belonged to the self in a way quite different from the shoe had not been mastered.[8] Preyer reported a series of explorations the little boy made discovering the outlines of his own head, the difference between his hand and the tray of his high chair. Fifty-five years later, Piaget's published studies of his three young children gave an account of the emergence of the idea of the object as a continuing entity apart from the perceiver. He concludes that the notion of the self as an object among objects was one of the achievements of the sensorimotor period.

The awareness that oneself is not merely one other object but has a special status is also attained in the early months of life. The toddler recognizes his own reflection in a mirror as a baby to whom he responds with interest as if to another child. By the time he reaches 18 months, however, he gives clear indication that the baby in the mirror is himself. This may come before he has enough language to express his understanding verbally, but his self-conscious little smile and his gestures make his meaning unmistakable. Thus, for a child even as young as this, one of the most complicated phenomena of psychic life has come into being (Stutzman). For a child at this time of life this demonstrates the maturation of self.

Recent research has inquired into the very earliest appearance of the style that will become the self. Mahler traces the gradual emergence of the individual from the autistic shell by which the newborn has been sheltered from excessive stimulation into "a protective but also receptive and selective positively cathected stimulus shield" that envelops a child-mother unity in the early normal symbiosis. After the healthful and necessary symbiotic stage is past, the infant gradually becomes aware, from two to nine months old, of the world outside the protecting shell and can attend increasingly to the world about him. The "holding behavior" of the mother, so indispensable for the protection of the neonate and young infant, can now loosen as the infant becomes ready to "hatch" from the symbiotic orbit smoothly and gradually without undue strain on his own resources. During the early infancy period a

circular interaction of cues goes on between the infant and mother in which the child gradually alters his behavior in a characteristic way. His emergent mode, Mahler writes, grows out of his own endowment and the mother-child relationship. Already "certain overall qualities of the child's personality" are discernible. What we seem to see here is the birth of the child as an individual. In the mutual cuing of mother and child the groundwork is laid for the "infant's becoming the child of his particular mother."

Mahler recounts the processes of separation and individuation, noting periods of heightened vulnerability. Optimal maturation will bring the young child to readiness for both physical and psychic distance from the mother. This stage is reached when ego functions have reached a fairly advanced stage and, equally important, when he has attained the level of object constancy in which the object is intrapsychically available. His memory of the mother, his cognitively held assurance of her existence and availability even when she is physically invisible, sustains him in his separateness. Clearly the timing of this maturation cannot be dated precisely, for the intricate network of competencies that enable the child, or older person, to exist without panic is made up of many strands and can be weakened by the failure of any one of them. Yet some children exhibit very early in life—even in infancy—an unusually strong thrust toward mastery. Mahler's reference to innate endowment is well-taken, for a characteristic level of directed energy is immediately interactive with environmental circumstances. This is

apparently an original given. A strong core of self thus seems present almost at birth.

Before nursery school age individual differences in the strength and clarity of self are apparent. The three year old with a firmly developed self can tolerate brief separation from his mother without great anxiety and, in achieved inner cohesiveness, is able to grasp the opportunities offered by the nursery school. As he advances into the school years, his life style is elaborated and his mold as a person is more firmly established. His achievements and failures, his acceptances and rejections are assimilated. The psychologically mature self during latency, building upon an already developed identity, is modified to include awareness that the self has at its command both a range of capabilities and the power to master increasing difficulty and scope as occasions require.

With each epoch in the growth cycle, changing biological structures, functions, and social roles call for reorganization of the existing self. Evidence on adult life for periods as long as 15 to 20 years indicates that the level of relative maturity and the trajectory of purpose is maintained. The extent to which life style remains essentially unchanged over the entire life span is still to be determined, but the evidence from longitudinal work encourages the hypothesis that those who have over the years been mature personalities will be so to the end (Cox)

The concepts and terms clustering around the self have generated research and stirred extensive discussion. Particularly germane to our purposes here are the ideas expressed by self- or ego identity, self-esteem, and self- or ego ideal.

The Self Known to Itself

The establishment of an identity recognizable to and accepted by the self as its own is a facet of the development of all persons and is not a property of only the psychologically mature. As in so many other facets of his makeup, the notably healthy individual is clearer about his identity and maintains it more steadfastly than the immature one does. Heath experimentally induced mild uncertainty about self- image in his immature and mature subjects and found the mature better able to withstand disturbing evidence.

Identity, nonexistent at birth, evolves as the infant defines himself in terms of his genetic idiom and also in terms of the responses he gets from others. Soon after extrauterine life begins the child identifies the self as male or female, and later still as a good or poor game participant, as a quick or slow learner. Similarly he understands his meaning in belonging to a particular family, race, social and national group. Only much later does he grow into his basic identity as a member of the family of man.

To be sure, there are certain normal and inevitable crises in the life cycle that shake identity. These are known to be associated with puberty, childbirth, and the climacteric as well as the socially produced trauma of vocational retirement and the dislocations following revolutions and wars. In such experiences complex supports of identity change drastically or are lost. One of the tests of maturity is the way the assurance of what one really is holds up.

A distinction is drawn in some of the research between the private and the social self.[9] In health the self is not wholly dependent upon the way one is conceptualized by others, but there is evidence that in the mature person there is congruencc between what one feels himself to be and how he believes others view him. Furthermore, he is pretty accurate in his estimate of the way he appears to others (Heath). Here both integration and realism operate.

Self-Esteem

Capacity to love unreservedly in the most intimate relationships and readiness to turn outward in disinterested generosity to the whole range of human relationships is said to have its roots in love of self. This sentiment is given various names by personality theorists: self-esteem, self-regard, self-love. It is necessary, of course, to be clear that self-love is not the same as selfishness or self-centeredness. Fromm has been at some pains to make this

distinction. Maslow found self-love to be "synergic with rather than antagonistic to love of others." Beneath the outreach to others that psychologically mature persons without exception show, we find a basic peace with the self (Cox, Fromm, Heath, Maslow). Pride in achievement, conviction of one's worth, and confidence that one is worthy of love enable the individual to extend the largesse of his disinterested care beyond the bounds of his own particular concerns. To entertain these feelings about oneself does not go hand-in- hand with smugness. Rather this attitude might be likened to that of the good strict parent described by Susan Isaacs—accepting and warm but not uncritical nor negligent about responsibility and future growth. In sum, the psychologically mature are found to be favorably disposed and cherishing toward the totality of what the self has been able to make of its quantum of life.

Self-Ideal

The significance of the self-ideal as a magnetizing force in moving the person toward as yet unachieved goals and levels of being is emphasized by various theorists. Lynd is especially clear about the place of this dynamic in personality: "It is readily apparent that the ideal of who one might or desires to be or become has important bearing on one's feeling about who one is." The self-ideal by definition reaches outside of and beyond the achieved state or self-image but is included in the sense of who one is. To aspire to

excellence, to strength, to saintliness is to claim kinship with these qualities and to borrow some of their effulgence. At the same time, unless there is intention and effort toward bringing the ideal self to reality, the ideal can become a substitute for striving. We see this in poorly integrated children who, when asked to set a goal, place it so far beyond anything they could possibly attain that they neutralize the pull of the goal (Cox). However, in realistic and responsible persons, from childhood onward the idea of what one wishes and tries to become exercises significant influence and is, indeed, an inalienable part of self.

The Mature Person

In the course of change and in the maintenance of stability, certain characteristics mark the psychologically mature individual, distinguishing him from the immature. Although the list of characteristics could be indefinitely extended, I would like to suggest the following trends or themes as most nearly universal and timeless: firm anchorage in reality, warmth and caring for other persons from an increasingly giving posture, productivity in work suited to ability, responsibility toward the small and the large social group, secure sense of self, development of a value system, and resilience under stress.

Notes

[1] The work of Heinz Werner, though in many ways paralleling that of Piaget, has until recently been less well known. His theory of mental development evolved over 40 years ago into an abstract formulation in which he confronts the problem of stability in the presence of ongoing change. His teaching at Clark University profoundly influenced his students. Piaget's enormous impact on American psychology has in a sense made developmental psychologists more aware of Werner.

[2] Stimulus-response learning theory and methodology have produced a vast literature that bears a tangential relationship to cognitive psychology and through cognition to the holistic interpretation taken in our approach to psychological maturity. S-R learning work dealing with small bands of behavior emitted by subjects responding to strictly controlled stimuli stands, however, in sharp contrast to the genetic approach, which has proved more useful in the understanding of persons as functioning wholes. White's

excellent review of the S-R learning theory tradition in relation to developmental psychology is illuminating.

Operant conditioning as a therapeutic method is, of course, an application of S-R learning theory, as is Skinner's contribution to education in machine teaching. These topics are dealt with more appropriately in another chapter of the handbook.

[3] The neglect of the retarded by psychiatry is currently being remedied to some degree by the implementation of comprehensive mental health programs. Public and private education and the multifaceted program of the National Association for Retarded Children have undertaken the habilitation—as distinct from rehabilitation—of this group and will probably continue to do so under comprehensive mental health care with more adequate support and overall coordination.

[4] Psychology as a science has shown marked reluctance to study tender, affiliative relationships. Allport notes that Ian Suttle sees this as a "flight from tenderness" spurred by the fear of seeming sentimentality. Despite the general taboo, investigators of psychological health have found love relationships to be a central theme in the lives of their subjects.

[5] Research on very vigorous physical exercise by subjects in their eighties has produced very promising results at the Lankenan Hospital, Philadelphia.

[6] Note particularly such people as Pablo Casals and Picasso in the arts, Hilda Smith in public service, and Lily Taylor in classical scholarship.

[7] Allport's eightfold schema for the proprium—or the self—includes the following: bodily sense, self-identity, ego enhancement, ego extension, rational agent, self-image, propriate striving, and the proprium as knower (pp. 41-62).

[8] A series of baby biographies and other less extensive reports touch upon these same phenomena, although few prior to Piaget have clone so with details as telling as Preyer's.

[9] Identity is regarded by some investigators to be so deeply related to social factors that it has no existence apart from them. They see it as a personal-social phenomenon. This would lead to the conclusion that there is no such thing as a private identity.

PART III
The Life Cycle and Its Common Vicisstudes

Chapter 10

The Life Cycle: Introduction

Theodore Lidz

The psychodynamic understanding of the personality and its disorders rests heavily upon the study of the life cycle. The commonalities and similarities in the course of all lives make possible the generalizations and abstractions necessary for the scientific study of the personality. Although no two persons are identical and no life stories are the same, the basic themes are limited and it is the variations upon them that are infinite and inexhaustible. Behind their individual uniqueness all persons are born with physical endowments that are essentially alike and with similar biological needs that must be met. Like all living things, they go through a cycle of gestation, maturation, maturity, decline, and death. In common with all humans, each individual starts life totally dependent on others and remains immature and dependent for many years, during which he forms intense emotional ties to those who nurture him —bonds that must be loosened sufficiently to enable him to live without them and to form new meaningful relationships. He requires many years not only to mature sexually and physically but also to learn the adaptive techniques he

needs to survive and guide his life; and he depends upon a society to provide his essential environment. He possesses the unique human capacities for language and tool bearing, and he depends upon verbal communication for collaboration with others, upon thought and foresight, and upon his ability to change his environment to meet his needs. Alone among animals he is aware of death and his position in his course from birth to death. Man's life is never static, for the passage of time of itself changes his functioning. Each phase of the life cycle brings new potentialities and closes off old ones; the opportunity and challenge must be met and surmounted for the individual to be prepared for the next phase.

Phasic Nature of the Life Cycle

The development of the personality and the course of the life cycle proceed phasically, not at a steady pace. The child goes through periods of relative quiescence during which his progress seems slight and then undergoes marked changes as he enters a new phase that opens new potentialities, provides new areas to explore, and sets new tasks that require the acquisition of new skills and abilities to master. Thus, the ability to walk, which must await maturation of the infant's nervous system as well as sufficient practice, changes the limits of the child's world and his perspective of his surroundings, as well as his relationships with his parents. He quickly gains new opportunities to explore and learn, but he also requires more

delimitation from those who take care of him. Similarly the hormonal shifts that precede and accompany the advent of puberty will move the child into a new phase of his life by rapidly altering his size and contours and by initiating unfamiliar sexual impulses.

The phasic nature of the life cycle derives from several interrelated factors.

Physical Maturation

The acquisition of certain capacities must await the maturation of the organism. The infant cannot become a toddler until the pyramidal tracts in the spinal cord that permit voluntary discrete movements of the lower limbs become functional around the tenth month. Even after maturation allows the acquisition of a new attribute, gaining the skill and knowledge to develop it can require considerable time and practice. Simple skills must be mastered adequately before they can be combined with others and incorporated into more complex activities.

In a related manner phasic shifts in the physiological balance of the organism initiate new phases in the life cycle. The metamorphosis of puberty that ushers in adolescence provokes changes without regard to prior developmental progress, and the menopause is likely to produce a basic reorientation in a woman's life.

Changes in the Individual's Cognitive Development and Decline

The child's cognitive development does not progress at an even pace. Qualitatively different capacities emerge in rather discrete stages and influence the child's capacity to assume responsibilities and direct his own life.

The Society

The roles the society establishes for persons of various ages set expectations that promote shifts in ways of living. The time of weaning and bowel training, for example, are markedly influenced by societal norms. Becoming a married person or a parent involves socially set expectations such as rescinding areas of independence to care for and consider the needs of a spouse or a child. Yet for a society to remain viable, the roles and expectations it establishes must be compatible with a person's abilities and needs at each phase of life. A child is moved into the role of schoolchild, with its many demands and privileges, at the age of five or six partly because primary socialization is usually completed and partly because his cognitive capacities have reached the stage of "concrete operations."

The Passage of Time

Not only does the individual move into age- appropriate roles, but time

brings changes in physical makeup that require changes in attitudes, as when a person reaches middle life and realizes his life is approaching a climax, or when diminished abilities lead to retirement.

The Epigenetic Principle

The epigenetic principle maintains that the critical tasks of each developmental phase must be met and surmounted at the proper time and in the proper sequence to assure healthy personality development. The principle was adopted by psychoanalysis from embryology. The birth of a normal infant depends upon each organ's arising out of its fetal anlage in the proper sequence, with each development depending upon the proper unfolding of the preceding phase. Personality development is, however, not as rigidly set as embryonic maturation, and even though development is impeded when a developmental phase is not properly mastered, compensations are possible and deficiencies can sometimes be turned into strengths. It is clear that a child who does not gain adequate autonomy from his mother prior to going to school will have difficulties in attending school, learning, and relating to peers, but failures are usually partial and not productive of an irremediable anomaly as in the embryo.

Progression, Fixation, Regression

Every life contains a series of developmental crises that arise from the need to meet the new challenges that are inherent in the life cycle. The individual gains new strength and self-sufficiency through surmounting these crises. Similarities exist in the ways in which different people meet similar developmental problems, and there is likely to be something repetitive about the ways in which the same person surmounts certain crises in his life.

Often there is a pause or delay before the child finds the confidence to attempt to face the strange needs of a new phase in his life. The need for emotional security sets limits on the pace of development. He is often prey to opposing motivations. There is an impetus toward expansion and mastery of new skills and situations and the child wishes to emulate parental figures, become more grown up, and achieve greater independence; but the new situations and demands bring insecurity, failures create frustrations, and greater independence requires renunciation of the comforts of dependency. The anxieties that are aroused can lead the child to seek the security of known ways and to renounce temporarily further forward movement, or even to fall back upon increased dependency.

A child requires guidance and support to progress properly. At times he may need to be checked from the unrestrained use of new capacities as when he begins to walk or when he first matures sexually, but at other times he may need support or even some prodding to move forward as when he is reluctant

to leave the familiar and protected home to attend school. Developmental hazards exist on both sides; too much support may leave the child overly dependent and fearful of venturing forward; too little can leave the child struggling to keep afloat.

The failure to cope with and master the essential tasks of a developmental phase leaves the child unprepared to move forward into the next phase. The child gives up, or more commonly he moves ahead in some areas and remains stuck in others. He squanders energy in coping with old problems instead of moving on. A child who has never felt adequately secure at home continues to seek maternal protection and affection when his peers are secure with one another. Such arrests are termed *fixations.* Movement backward to an earlier developmental phase in which the child felt secure is termed *regression.* Paradoxically regression is a normal aspect of the developmental process, for every child will regress at times in order to regain security or to reestablish his equilibrium after feeling defeated. The small child tends to progress securely when he feels that he can find parental protection at the center of his expanding world should he need it.

Even though fixations and regressions are important means of maintaining or regaining emotional security, they create insecurities in turn if they are not simply temporary expediencies. The child remains improperly prepared to meet the developmental challenges of the next phase of the life

cycle and is unable to accept the opportunities afforded him. Even though the child is pulled in two directions, the motivations to move forward are normally more powerful. He is carried onward by his growth, by impulsions for the stimulation of new experiences, by his drives, by needs for the affection and approval of his parents, by desire to go along with his peers, by the yearning of his body for another, by the needs of survival, by the roles provided by society, by the desire for progeny, and by other such influences.

The Divisions of the Life Cycle

The life cycle has been divided into stages or phases somewhat differently by various students of the developmental process; some of the differences reflect differing purposes in making these divisions, and others reflect differing theoretical orientations and conceptualizations of human development. However, despite differences in theory and terminology, there is considerable overlap in where the dividing lines are placed. The description and study of the salient features of these stages have evolved largely from four rather different approaches to understanding the phasic emergence of essential attributes of the personality: those of Freud, Sullivan, Erikson, and Piaget. As the contributions of Freud and Sullivan are described in detail in other chapters, only Erikson's and Piaget's approaches will be discussed here.

Erikson's Phases of Psychosocial Development

Adhering to a more classical psychoanalytic framework than Sullivan, Erikson superimposed an epigenesis of psychosocial development upon the psychosexual phases. He designated what he considered to be the critical psychosocial task of each phase that the individual must surmount in order to be properly prepared to meet the opportunities and tasks of the next stage. He also went beyond the traditional psychosexual phases that end with the "genital phase." In particular, he emphasized the critical moment of late adolescence, when the personality must gel and a person achieve an ego identity. He then continued to consider the developmental problems of adult life. He has formulated eight stages of psychosocial development, focusing upon the specific developmental tasks of each stage and examining how differing societies help the individual to cope by providing essential care, promoting independence, offering roles, and by having institutionalized ways of assuring survival, proper socialization, and emotional stability. Meeting and surmounting the developmental task of a period leads to the acquisition of a fundamental trait essential for further stable development, whereas failure leads to an enduring deficiency.

As the infant is almost completely dependent upon others to satisfy his vital needs and to keep him comfortable, the basic psychosocial task of the oral phase concerns the achievement of a basic trust in others and also in the self, with failures leading to varying degrees of basic mistrust; the "basic" conveys that the trust is not conscious but blends into the total personality

and forms an inherent component of it. The emphasis of the anal phase or the second year of life is upon the attainment of muscular control in general rather than upon bowel control in particular. In learning self-control during this phase, the child properly gains a lasting sense of autonomy; on the other hand, failure to achieve self-control often leads to a pervasive sense of doubt and shame. The resolution of the oedipal conflict during the phallic phase leads to a heightening of conscience; it is the time, too, when the child needs to develop the prerequisites for either masculine or feminine initiative or become prey to a deep and lasting sense of guilt. In the latency period the child starts school where he finds that gaining admiration, approval, and affection depends upon achievement, and now he must acquire a capacity for industry or become subject to a pervasive sense of inferiority. Then, instead of emphasizing the relationship between genital sexuality and emotional maturity, Erikson focuses upon the need to attain an ego synthesis by the end of adolescence that affords a sense of ego identity, "the accrued confidence that one's ability to maintain an inner sameness and continuity is matched by the sameness and continuity of one's meaning for others. If this cannot be attained the person is subject to identity diffusion. Then, after the young adult has achieved a sense of identity, he can move to relate to another with true intimacy and have the concomitant capacity to distantiate the self from persons or forces whose essence is dangerous to his own; failure to gain the capacity for intimacy almost inevitably leads to self-absorption. The next

phase of adult life has as its critical issue the interest in producing members of the next generation and guiding and laying foundations for it; that is, a capacity for generativity, with stagnation as the negative outcome of the phase. The final phase of the life cycle concerns the achievement of mature dignity and integrity through maturely accepting "one's own and only life cycle" and taking responsibility for how it has turned out, whereas despair involves the feeling that this one chance has been wasted and, in essence, has been worthless.

The specific dichotomies that Erikson has utilized to characterize the critical issues of each developmental phase sharpen his emphasis upon the need to cope with tasks rather than simply to pass through a phase without suffering traumata that cause fixations. Still, the critical issues selected neglect other developmental tasks and personality attributes that would seem just as significant.

Piaget and the Epigenesis of Cognitive Development

The theory that we have been considering is not explicitly concerned with the person's linguistic and cognitive development, even though these capacities are essential to what is uniquely human in personality development. Fortunately Piaget, because of his interest in epistemology, sought to uncover the psychological foundations of knowing. The

development of intellectual functioning, including language, reasoning, conceptualizing, and categorizing, have been examined, and concomitant studies of the child's moral development have also provided new insights. Cognitive development is conceptualized in strictly epigenetic terms. Piaget and his co-workers have traced the ever increasing scope of the child's abilities through the constant process of adaptation of the existing state of the organism to new experiences. The child cannot utilize experiences that his cognitive schema are not yet ready to assimilate. The foundations for experiencing emerge step by step through the expansion and reorganization of prior capacities as they take in new experiences, thus becoming prepared to react to and utilize more complex experiences. The process is a very active one in which the organism is, so to speak, ever reaching out to incorporate new experiences within the limits permitted by its organization at that moment in its development. Piaget's observations are of great importance to any conceptualization of the life cycle because they provide guides to how the child and adolescent regard the world and can think about it at each stage of development.

Piaget has divided cognitive development into four major periods, each of which is subdivided into various stages and substages. The *sensorimotor* period lasts from birth through the first eighteen to twenty-four months and is essentially concerned with the child's preverbal development. The child's ways of interacting with the world are traced step by step from the neonate's

reflex movements through the time when the child uses internalized visual and motoric symbols to invent very simple means of solving problems. In the *preoperational*period, which lasts until about the time the child enters school, the child becomes capable of using symbols and language. He will not yet have the ability to adapt what he says to the needs of the listener, to note contradictions, or to construct a chain of reasoning. During this period he moves beyond his static ways of thinking as he gains experience and as words begin to symbolize categories. The period of *concrete operations* approximates the "latency" period, lasting from about the start of schooling to the onset of puberty. The child now possesses a coherent cognitive system with which he can understand his world and into which he can fit new experiences in a rather ordered fashion. He can carry out simple classifications, but he is not yet capable of abstract conceptualizations. The period of *formal operations* starts in early adolescence when the youth becomes capable of thinking in propositions, using hypotheses, and carrying out operations that are abstracted from concrete examples. Formal operations may require considerable formal education, for only exceptional persons appear to reach this stage on their own.

A Comprehensive Orientation to the Phases of the Life Cycle[1]

It is not always feasible to sum up the various tasks of a developmental phase under a common rubric, nor is it always wise, for it can convey an

oversimplification of a very complex process. Various aspects of the personality develop at differing tempos, and it is essential to study each developmental line separately. The interrelationships between the development of such essentials as cognitive abilities, ethical concepts, object relationships, self-concepts, and gender identity require continuing study. Still, dividing the life cycle into a series of rather natural phases permits the comparison of the various developmental lines, and how an individual's development may be globally or partially impeded, fixated, or regressed at a given phase in development.

Infancy

The period of infancy approximates the first fifteen months of life when the baby is almost completely dependent upon others to care for his essential needs, to provide a sense of security and the stimulation required for his proper emotional and cognitive development. The psychoanalytic term "oral phase" emphasizes that the infant's life centers upon taking in nutriment through sucking but also that his emotional well-being rests upon the assimilation of feelings of security from those who nurture him. If his essential needs are filled and untoward tensions do not repeatedly arise within him, he will have established at the core of his being a basic trust in the world and those who inhabit it. It is upon this trust in others that confidence in himself and in his capacities to care for himself will later develop. Still, a

great deal more than gaining a sense of basic trust and a satisfaction of oral needs must take place if the infant is to develop properly. These are a very long fifteen months during which the child undergoes a greater physical and developmental transformation than at any other time in life. So much occurs that we may doubt the wisdom of considering it as a single developmental period. Indeed, there are profound differences between the first and second halves of infancy. During the first half, particularly during the first four months, the baby's physical maturation is of dominant importance, and the care of the child's physical needs takes precedence. Relative neglect of socializing and affectional care can probably be neutralized by later efforts, but such needs cannot be neglected during the second half of infancy without producing permanent effects. With adequate security and proper stimulation from those who raise him, the child will complete most of his sensorimotor development to gain increasing control over his movements, to differentiate himself from his environment, and to experiment with ways of manipulating it. He learns to crawl, and as he begins to toddle and as his babbled jargon turns into words, he moves into a new phase of development.

The Toddler

As the baby begins to walk and talk, he enters the new phase in which the crucial problems involve the imbalance between his newfound motor skills and his meager mental capacities. He is impelled to use his new abilities

to explore his surroundings, but limits must be set upon his activities for his own safety. Because of his limited verbal and intellectual capacities reasons cannot be explained to him, and the baby is only beginning to tolerate delays and frustrations. The delimitations and the increasing expectations for self-control almost inevitably lead to some conflict with the nurturing persons and can provoke stubbornness, negativism, withholding, and ambivalent feelings toward parental figures. The phase is critical to establishing a basic trust in the self and a sense of initiative. Too much delimitation and fostering a fear of exploration can stifle initiative and the development of self-confidence. Mothers who overestimate the toddler's capacities to conform and who cannot tolerate disorder can easily instill a pervasive sense of guilt or shame. The struggle over conformity often focuses upon bowel training and thereby can involve anal erotic fixations. During this period the child requires subtle guidance in the complex process of acquiring language and a trust in the utility of language. Now the child is also gaining a firm sense of being a boy or a girl, and after the age of three the child's gender identity cannot be reversed without leaving considerable sense of confusion. During this phase the child's life interdigitates so closely with his mother's that prolonged separation from her affects him profoundly, causing physiological and depressive disturbances. When the child is about three years old, the period comes to a close; a reasonably good equilibrium has been established between his motor skills and his ability to comprehend and communicate

verbally. If progress through the period has gone well, he is ready to gain a more definite autonomy from his mother and find his or her place as a boy or girl member of the family.

The Oedipal or Preschool Child

Some time around the age of two and a half or three, the child ceases to be a baby and becomes a preschool child and begins to go through a period of decisive transition. The infant and toddler had required a close and erotized relationship with his mother, but now the erotic aspects of the relationship must be frustrated to enable the child to gain a more realistic and less egocentric grasp of his place in his mother's life. The transition depends partly upon his mother's ability gradually to frustrate her child's attachment to her, but also upon other changes that are taking place. This phase is critical to the eventual achievement of autonomy. At the end of it he will have completed the tasks of primary socialization, accepted his place as a child member of the family, and be prepared to invest his energies and attention in schooling and in activities with peer groups. Early in this developmental phase the boy experiences his father as an intruder into his relationship with his mother, develops hostile feelings toward his father, and fears reciprocal hostility from him. He properly regains an emotional equilibrium by rescinding his primacy with his mother and seeking instead to become a man like his father, a person capable of gaining the love of his mother. The girl, in

giving up her basic attachment to her mother, usually finds a new primary love object within the family in her father and forms a close attachment that will be rescinded about the time of puberty. The child is now gaining the experience as well as the cognitive tools he needs for improved reality testing, and an important aspect of the period is the differentiation of fantasy from reality. He also properly gains a trust in the utility and validity of verbal communication as a help in solving problems and in collaborating with others. His ego function, his ability to guide himself, thus progresses considerably and is further strengthened as he internalizes parental directives. By the age of five or six the child will have gained considerable organization of his personality, and the major lines of his future development will have been laid down—his ways of relating to others and reacting emotionally, having been patterned within his family setting. The resolution of the oedipal situation terminates early childhood, and the precise manner in which the oedipal situation or "family romance" is worked through sets a pattern that will be relived in later interpersonal relationships. During these few years the child has taken a giant step toward becoming an independent and self- sufficient person even though he has done so through appreciating the long road ahead before he can attain adult prerogatives.

The Juvenile

The equilibrium the child gained within his family is disrupted as he

goes off to school, where he will be judged by his achievements rather than by ascription, and as he spends increasing amounts of his time with his neighborhood peer group, where he must also find his place on his own. As Erikson has noted, unless the child now gains a sense of industry, he can develop pervasive feelings of inferiority and inadequacy. The trait of industry is encompassed, on the one side, by the danger of habitual compulsive striving to excel competitively and, on the other, by defeatist trends with unwillingness to face meaningful challenges. Other traits also have their roots in this time of life. A sense of belonging develops, the feeling that one is an accepted integral part of the group as contrasted with the feeling of being an outsider; it is a sense that not only concerns social ease as contrasted with social anxiety, but ultimately affects the person's identification with the society in which he lives and his commitment to its values and ethics, as contrasted with a deep- seated feeling of alienation. It is now that a sense of responsibility begins to develop, which involves the willingness to live up to the expectations that one arouses in others. The child's self-concept begins to crystallize in reaction to the way his teachers and peers relate to him. At about the time the child enters school, there is a notable shift in his cognitive processes as he moves into Piaget's stage of concrete operations; and his moral judgment matures from a morality of constraint that is based upon adult edicts to a morality of cooperation. Although psychoanalytic theory considers this time of life as the latency period, it is apparent that these early

school years are critical to the child's socialization and the development of many personality characteristics as he begins to move beyond the shelter of the home into the broader world of the schoolroom and his peer groups.

Adolescence

Adolescence may be properly defined as the period between pubescence and physical maturity, but in considering personality development we are interested primarily in the transition from childhood to the attainment of adult prerogatives, responsibilities, and integration. Adolescence involves the discrepancy between sexual maturation and the physical, emotional, and social unpreparedness for commitment to intimacy and the responsibilities of parenthood. Usually it involves an inner struggle to overcome dependency upon parents, which is reflected in an outer struggle to assert independence from parental authority. The adolescent goes through the difficult process of gaining freedom from the earlier repressive ban upon sexual expression while redirecting his choice of love objects outside of the family circle. During these years his cognitive capacities change, and he enters Piaget's stage of formal operations; he becomes capable of using propositional logic, can think about concepts abstracted from reality, and is able to utilize hypothetical-deductive thinking. Ethical or moral capacities also develop as the adolescent becomes interested in ideas, ideals, and ideologies, and his behavior is apt to be directed by the values of the social

system rather than simply by interpersonal relationships and the values stemming from them. At the start of adolescence the individual is still a child at play, dependent on his parents and with an amorphous future; at the end he becomes responsible for himself, the direction his life will take is fairly well settled, and his personality has gelled into a workable integrate. As Erikson has properly emphasized, the primary task of adolescence concerns the attainment of an ego identity, but usually, particularly for a girl, the attainment of an ego identity also requires the gaining of a capacity for intimacy.

The lengthy period of adolescence can usefully be divided into three subphases. Early adolescence includes the reorientation required by the prepubertal spurt of growth as well as the physical changes and altered impulsions and feelings that come with puberty. Midadolescence, which is likely to begin twelve to eighteen months after pubescence, is an expansive period. It includes movement toward the opposite sex, which leads to a realignment of intimate friendships. Characteristically it is a time of revolt and conformity, revolt from parental standards and authority and conformity to peer group standards and loyalties. Late adolescence is usually a time when delimitation is required as the young person seeks to find and define his own identity and when cravings for intimacy with a specific individual become important.

Youth

Keniston has suggested that we are currently experiencing the emergence of a new developmental phase among some young people, which he suggests we designate as "youth." It may seem strange to insert a new phase in the life cycle, but the course of the life cycle varies with the social and cultural setting. Aries has pointed out that during the Middle Ages childhood stopped at the age of six or seven. Adolescence may not have been a major developmental stage until secondary school education became common early in this century. Among many preliterate peoples the child becomes an adult shortly after puberty by means of initiation ceremonies. Currently the inability to depend upon traditional ways of adapting in a rapidly changing world has created new developmental problems for some highly educated youths.

Youth includes the period that usually has been included as part of late adolescence and early adult life. It concerns the tensions between the self and society, with a reluctance, or a refusal, to accept either conventional societal standards or a conventional role in society—the "social contract" cannot be accepted if it conflicts with a personal morality based upon higher principles. Critical to this stage of life may be the new awareness of how greatly a person's traits and potentialities depend upon the social environment in which he has been raised as well as upon the ethical standards he embraces.

The period is marked by a struggle against acceptance of a conventional way of life and sometimes by a reluctance to accept commitment to a single way of life that will make one an adult. The dangers quite clearly lie in the extremes of alienation—alienation from society, instead of reasonable acceptance of it, or alienation from the self with a pathological self-absorption and withdrawal from considerations of reality.

The Young Adult

The young adult is at the height of his physical and mental vigor, and his energies and interests can now be directed beyond his own growth and development. He has become reasonably independent of his natal family, and having overcome blocks to intimacy with a member of the opposite sex, he is ready to establish a new interdependence with another person and to find his place in the social system. Now commitments are made, and if a person cannot make them he will lack the opportunity of being meaningful to others and having others become meaningful to him. Occupational choice and marital choice, if not made previously, are critical issues, and both will greatly influence the further course of his life cycle. Choice of an occupation determines much of the physical and social environment in which a person will live; it selects out traits that are utilized and emphasized; it provides social roles and patterns for living; and by determining the sort of persons with whom one spends much of his life, it markedly influences values and

ethical standards. The choice of a spouse constitutes the major decision that can complement or alter the personality makeup before the production of a new generation. In marrying, one gains a partner who shares, supplements, and supports and upon whom one can rely because the well-being of each partner is bound up with the fate of the other. Marriage also helps individual integration by providing a way of life for which there are traditional directives and a place in the social system. Marital adjustment provides a major test of personality integration and organization, for it requires the malleability to interdigitate one's drive satisfaction, way of life, and ethical standards with a person raised in another family. Marriage not only tests the success of the earlier oedipal transition but also many other facets of the developmental process.

Parenthood

The position of parenthood in the life cycle is not fixed, but for most it comes after commitment to marriage and when the process of self-creation is more or less completed. Spouses are transformed into parents and their marriage into a family. The birth of the first child often alters their life patterns and perspectives more than had their marriage. The person who becomes a parent usually gains a new sense of achievement and completion by the act of creativity. Women, in particular, now feel fulfilled, for to many their biological purpose seems to require completion through conceiving,

bearing, and nurturing children and strong cultural directives had added moment to such desires. The woman's creativity as a mother becomes a central matter that provides meaning and balance to her life; and for many years her child or children will be a prime focus in her life. The birth of a child also brings increased self-esteem and sense of responsibility to the father. Parenthood often provides a severe test of the integration of a parent's personality and capacities to accept responsibility for dependents. The child forms and will long continue to form a bond between the parents, a source of shared interest and identification, but he can also be a divisive influence, and in each marriage may in different proportions and ways be a unifying and separating force. For those who have achieved the necessary capacities, the new responsibilities are offset by the fulfillment that comes with experiencing the other side of the parent-child relationship; the self-realization that derives from being needed and loved by a child to whom the parent is so very important; and the constant renewal that comes with the changes in the offspring.

The Middle Years

The passage over the crest of life is a particularly critical period. It is a time of stocktaking concerning the manner in which the person's one and only life is passing—the gratifications attained from marriage and career, and an assessment of prospects for the future. The turn into middle life involves a

state of mind rather than some specific bodily change or some clearly demarcated shift in life roles, although awareness of wear and tear on the body and increasing incidence of chronic illness, incapacitation, and death among peers influences the state of mind. The new phase starts with a persistent awareness that it will soon be too late to attempt to change one's course through life. For women in particular middle age may start when the children leave home, or at least no longer require a major share of her attention. Middle age for the woman contains the menopausal "change of life," but she is usually well into middle age when it occurs. A sense of integrity comes with the feeling that a life has been meaningful, that relationships with those who are significant are happy. A negative balance sheet can lead to changes in career or marital partners and frantic efforts for sexual gratification. Dignity, perhaps shaded by resignation, can ward off feelings of despair when life has not produced meaningful relationships or the prospect of achieving goals. As the person passes over the peak, he finds himself one of the older, responsible generation. Accepting responsibilities that one has achieved or has thrust upon one leads to further growth in contrast to stagnation. It is a time of fruition for some, but for others it is a time of regret and disillusion that often leads to resentments toward those who seem to have frustrated.

Old Age

Currently old age is somewhat arbitrarily considered to start at about the age of sixty- five, the time when most men retire from an active occupation. Many of the contemporary problems of the aged involve the difference between a desirable, unharried, and dignified closure of life and a hollow survival in which the person feels useless, unneeded, and burdensome. It is, or should be, a period of surcease from striving and a need to prove one's worth. A sense of equanimity requires the acceptance of failures as well as accomplishments. Sooner or later the aged person becomes increasingly dependent, and his contentment rests upon the reliability of those upon whom he must depend. In some respects there is a reversal of the attainments of adolescence: bodily strength and sexual desire decrease, secondary sexual characteristics and cognitive capacities wane, and concomitantly the pride and confidence derived from such attributes diminish.

It is useful to consider three phases of old age even though not all persons go through them. The elderly person is not greatly changed from middle life and considers himself capable of taking care of himself and his affairs. Eventually physical changes or alterations in life circumstances make him dependent upon others and he is considered *senescent.* The final phase, which many are spared, is *senility,* when the brain is no longer sufficiently intact to serve its essential function as an organ of adaptation.

Death

Death is the end of the life cycle and an inevitable outcome that brings closure to every life story. Because man is aware of this eventuality from an early age, it profoundly influences how he lives his life. The desire for some type of continuity into the future is pervasive, but the ways of seeking some semblance of immortality are diverse. The finite character of life provides delimitation by directing the individual to specific objectives, by countering diffuse and unbridled strivings, and by bringing a desire to provide a proper ending to a life. Death lends incisiveness to the meaning of experiences, sharpening appreciation of the transitory and the beautiful. Above all, it heightens the preciousness of those one loves because of their mortality. To those who have obtained some wisdom in the process of reaching old age, death often assumes meaning as the proper outcome of life. It is nature's way of assuring much life and constant renewal. Times and customs change but the elderly tire of changing; it is time for others to take over, and the elderly person is willing to pass quietly from the scene.

Panphasic Influences

The developmental process is also profoundly affected by influences that are not phasic. Children usually have the same parents throughout the first decades of their lives, and the parents' personalities and their ways of

relating to each other as well as to the child pervade all phases of the child's early development. While a parent may relate more salubriously or deleteriously at a given phase of a child's development, many such influences are panphasic. The parental models for identification, as well as the intrafamiliar milieu and the socioeconomic setting in which the family exists, can affect the individual throughout all developmental stages. Some of these panphasic influences will be presented in The Family: The Developmental Setting.[2]

Chapter 11

The Family:
The Developmental Setting

Theodore Lidz

Studies of personality development and maldevelopment have been seriously impeded by a dearth of understanding of the central role of the family in directing the developmental process. The critical early stages of the life cycle, upon which all later development and the stability of the personality rest, take place in the nidus of the family. The stability and satisfaction of the lives of most adults depend greatly upon their marital and parental transactions within their families of procreation. A very large proportion of the work in any dynamic psychotherapy is concerned with the reevaluation of parental influences and the reorganization of patient's reactions to them, so he can be freed from deleterious internalizations and transferences that interfere with his interpersonal relationships and his own evaluation of himself. The various childhood phases of the life cycle unroll favorably or unfavorably not so much be cause of innate characteristics as because of the manner in which the

parental figures and the intrafamilial transactions guide the child through the phase. Attempts to study the young child's development independently of the family setting distort even more than they simplify, for they leave out essential factors of the process.

Importance of the Family

Because the family is ubiquitous it has, like the air that we breathe, been very much taken for granted and many of the vital functions it subserves have been overlooked. Indeed the human being is so constructed that the family is an essential correlate of his biological makeup. It is the basic institution that permits his survival and his development into an integrated person by augmenting his inborn adaptive capacities. Man, after all, is virtually unique among animals in depending upon two endowments: he has both a genetic inheritance and a cultural heritage. His genetic endowment transmits his physical structure and his physiological makeup, which, as in all other animals, permits survival within a relatively narrow range of environmental conditions. Many of his critical adaptive techniques are not inborn; he is born with a unique brain that permits him to acquire language and thereby to acquire from those who raise him the instrumentalities that his society has developed for coping with the environment and for living with one another. This permits him to develop a personality suited to that specific society in which he grows up. The human mechanisms for survival and adaptation are

vastly different from those possessed by any other organism, and we can never understand human development and functioning properly unless we take full cognizance of man's dual heritage.

Everywhere the family must meet two requisites: the biological nature and needs of man, and the requirements of the particular society in which it exists and which it subserves by preparing children to live in it. Thus, wherever families exist they will have certain essential features in common even while handling similar problems in differing ways in accordance with the needs of a specific society. In this chapter, I shall seek to designate the essential functions of the family, particularly for childrearing, and the requisites for carrying them out.

The family is an essential correlate of man's biological endowment, for it is the basic social system that mediates between the child's genetic and cultural endowments, provides for his physical needs while instilling societal techniques, and stands between the individual and society, offering a shelter against the remainder of society. Because the child must remain dependent on others for many years, it is important that he be raised by persons to whom his well-being is as important as their own. His dependency upon them and his prolonged attachment to them provide major motivations and directives for his development. As the family forms the earliest and most pervasive influence that encompasses the still unformed infant and small

child, the family's ways are *the* ways of life for the child, the only ones he knows. All subsequent interpersonal experiences are perceived, consciously and unconsciously understood, and reacted to according to patterns laid down within the family. These family patterns and the child's reactions to them become so thoroughly incorporated in the child that they are difficult to differentiate from genetically determined factors with which they interrelate. This difficulty greatly complicates the study of the child's physical and personality development. Later influences will modify those of the family, but they can never undo nor fully reshape these early core experiences.

The Family's Primary Functions

The family is usually considered essential because of its childrearing functions, but we cannot properly understand either why the family is omnipresent or how it rears children unless we appreciate that it also subserves essential needs of the spouses and of the society. It not only fills a vital societal need by carrying out the basic enculturation of its children, but the family also constitutes the fundamental social unit of virtually every society: it forms a grouping of individuals that the society treats as an entity; it helps stabilize a society by creating a network of kinship systems; it constitutes an economic unit in all societies and a major economic unit in some; and it provides roles, status, motivation, and incentives that affect the relationships between individuals and the society. In addition, the nuclear

family completes and stabilizes the lives of the spouses who formed it. These three sets of functions of the family—for the society, for the parents, and for the children—are interrelated, and it is likely that no other institution could simultaneously fill these three functions without radical change in our social structure and probably not without grave consequences. It is even highly probable that these functions essential to human adaptation cannot be met separately at all except under very special circumstances, but must be fused in the family. Nevertheless, these functions can also conflict, and some conflict between them seems virtually inevitable. Fulfilling parental roles obviously often conflicts with a person's functions as a spouse, and society's demands can obviously conflict with the needs of both the spouses and children, as when the husband is taken from the home into military service.

The Purposes of Marriage

In order properly to grasp the nature of the family setting, it seems essential to examine briefly why people marry and form new families. Such considerations have particular pertinence at the present juncture in history when the value of the family is being challenged as part of the broader questioning of existing institutions and mores. Although people marry for many reasons—love, passion, security, status, to escape from the parental home, to have children, to legitimize a child—marriage is a basic institution in virtually all societies primarily because of man's biological makeup and the

manner in which he is brought up to reach maturity.

In growing up in a family, a person forms an essential bond to those who raise him, and he assimilates and internalizes their ways and their attributes. However, an individual cannot achieve completion as an adult within his family of origin. Minimally some degree of frustration must occur because he cannot become a parent with the prerogatives of parenthood and because sexual gratification cannot be united with his affectional relationships. Within his natal family, however, he has enjoyed the security of being a member of a mutually protective unit in which his welfare, at least theoretically, has been of paramount importance to his parents. When he leaves his family of origin, his emotional attachments to it remain unresolved, and he has strong conscious and unconscious motivations to bring closure to these emotional imbalances that move him toward a new union with a person who seems to fill the image of the desired complementary figure sufficiently to be transformed into it. He hopes through marriage to regain the security afforded by a union in which his well-being and needs are again of paramount importance to another—and in marriage the spouses' well-being and security are intimately if not irrevocably interconnected.

The division of the human species into two sexes has created another major impetus for marriage. Men and women are drawn together not only by sexual impulses but also because the two sexes complement one another in

many different ways. Males and females are subjected to gender-linked role training from earliest childhood, which gives them differing skills and ways of relating to people and regarding the world even if such differences are instigated by anatomical, genetic, and hormonal factors. Speaking broadly, neither a man nor a woman can be complete alone. The two sexes are raised to divide the tasks of living and to complement and complete one another as well as to find common purposes sexually and in raising children.

In a marriage the husband and wife can assume very differing types of role relationships and find very diverse ways of achieving reciprocity with one another provided they are satisfactory to both, or simply more satisfactory than separating. The variant ways in which marital couples live together are countless. However, when the birth of a child turns a marriage into a nuclear family, the spouses' ways of relating to one another must not only shift to make room for the children, but limits are also set upon how they can relate to one another if they are also to provide a proper developmental setting for their children.

The Family as a Small Group

Even though a marriage relationship is a very complicated matter, it can be studied and understood in terms of a dyadic interaction, including the influence of other persons and other situations upon the two marital

partners. A family, in contrast, cannot be grasped simply in interactional terms, for it forms a true small group with a unity of its own. The family has the characteristics of all true small groups, of which it is the epitome: the action of any member affects all; unless members find reciprocally interrelating roles, conflict or the repression of one or more members follows; to function properly the group requires unity of objectives and leadership toward these objectives; the maintenance of group morale requires each member to give some precedence to the needs of the group over his own desires; it has a tendency to divide up into dyads that exclude others from significant relationships and transactions. These and still other characteristics of small groups are heightened in the family because of the intense and prolonged interdependency of its members, which requires the family, in particular, to have structure, clarity of roles, and leadership to promote the essential unity and to minimize divisive tendencies. The family, moreover, is a very special type of group with characteristics that are determined both by the biological differences of its members and also by the very special purposes it serves. A designation of these characteristics can lead to an appreciation of why the structure of the nuclear family must meet certain requirements.

Generational Differences

The nuclear family is composed of persons of two generations, and the

members of each have different needs, prerogatives, obligations, and functions in the family. The parents who have grown up in two different families seek to merge themselves and their backgrounds into a new unit that satisfies the sexual and emotional needs of both and helps bring completion to their personalities in a relationship that seeks to be permanent for them. The new relationship requires the intrapsychic reorganization of each spouse to take cognizance of an alter ego. Wishes and desires of a spouse that can be set aside must be differentiated from needs that cannot be neglected. Although individuals, as parents they function as a coalition, dividing the tasks of living and childrearing. They are properly dependent on one another, but parents cannot be dependent on immature children without distorting the children's development. They provide nurturance and give of themselves so that the children can develop, serving as guides, educators, and models for their offspring even when they are unaware of it. As objects of identification and as basic love objects for their children, how the parents behave and how they interrelate with one another, and not simply what they do to and for their child, are of utmost importance to the child's personality development.

Children, in contrast to parents, receive their primary training in group living and in socialization within the family and are properly dependent upon their parents for many years, forming intense bonds to them while developing through assimilation from the parents and the introjection of their characteristics. Yet the children must so learn to live within the family that

they can eventually emerge from it into the broader society, or at least be capable of starting families of their own as members of the parental generation.

Gender Differences

The nuclear family is also composed of persons of two genders with complementary functions and role allocations as well as anatomical differences. The primary female role derives from woman's biological makeup and is related to the nurturing of children and the maintenance of the home needed for that purpose, which has led women to have a particular interest in interpersonal relationships and the emotional harmony of family members—an expressive-affectional role. The male role, also originally related to physique, traditionally is concerned with the support and protection of the family and with establishing its position within the larger society—an instrumental-adaptive role.

Intrafamiliar Bonds

The family relationships are held firm by erotic and affectional bonds. As the marriage is expected to be permanent, the parents are not only permitted but expected to have sexual relationships. Conversely all direct sexual relationships within the family are prohibited to the children; and even

the erogenous gratification from parental figures that properly accompanies nurturant care must be progressively frustrated lest the bonds to the family become too firm and prevent the child's investments of interests, energy, and affection beyond the family. The de-erotization of the child's relationships to other family members is a primary task of the family.

The Family as a Shelter

The family forms a physical and emotional shelter for its members within the larger society. However, the family must reflect and transmit the society's techniques of adaptation to its children including the culture's systems of meanings and logic, its ethos and ethics, to assure that the children will be able to function when they emerge from the family into the broader society.

These characteristics of the nuclear family, and corollaries derived from them, set requisites for the parents and for their marital relationship if the family they form is to provide a suitable setting for the harmonious development of their offspring and for directing their development into reasonably integrated adults.

The Parental Requisites

In considering the family's essential functions in regard to the

development of its children, it is of critical importance to recognize that the child does not grow up to attain a mature, workable personality simply through the nurturance of inborn directives and potentialities;

he does not simply develop into an integrated and adaptable person unless fixations occur because of some innate tendency, some emotional trauma, or some flaw in maternal nurturance during the early years of his development. The child requires positive direction and guidance in a suitable interpersonal environment and social system. The positive molding forces have largely been overlooked because they have been built into the institutions and customs of all workable societies and particularly into the family, which has everywhere knowingly or unknowingly carried out the task of shaping the child's development. The family fosters and organizes the child's development by carrying out a number of interrelated functions, which I shall consider under the headings of *nurture, structure,* and *enculture.* We must examine the nature of these essential functions to understand human personality development and its aberrations properly.

Nurture

The parental nurturant function must meet the child's needs and supplement his immature capacities in a different manner at each phase of his development. This is the one function of the family that has been specifically

recognized by most developmental theories. As it has been the focus of intensive study, it does not require elaboration here. It concerns the nature of the nurturance provided from the total care given to the newborn to how the parents foster adolescent movement toward independence from them. It involves filling not only the child's physical needs but also his emotional needs for security, consistency, and affection; and it includes furnishing opportunities for the child to utilize new capacities as they unfold. Proper nurturance requires the parents to have the capacities, knowledge, and empathy to alter their ways of relating to the child in accord with his changing needs. The capacity to nurture or to be maternal is not an entity. Some mothers can nurture a child properly so long as he is almost completely dependent but become apprehensive and have difficulty as soon as he becomes a toddler and cannot be fully guarded from the dangers in his surroundings; some have difficulties in permitting the child to form the erotized libidinal bonds essential for the proper development of the preoedipal child, whereas others have difficulty in frustrating the child's erotized attachment during the oedipal phase. However, unstable parents and grossly incompatible parents are often disturbing influences throughout all of the child's developmental years, and such panphasic influences are often more significant in establishing personality traits or disturbances in children than are fixations at a specific developmental phase. While the mother is usually the primary nurturant figure to the child, particularly when the child

is small, and though she is usually the family expert in childrearing and child care, her relationship with the child does not transpire in isolation but is influenced by the total family setting. The mother's capacity to care for her child properly is influenced greatly by her marital interaction with her husband, by the demands of other children, and by the relationships between her children as well as by her husband's relationship with each child. The quality and nature of the nurture that a child receives profoundly influences his emotional development. It affects his capacities to differentiate from the mother and the emotional context of his relationships to others; it affects his vulnerability to frustration and the anger, aggressiveness, anxiety, hopelessness, and helplessness he experiences under various conditions. As Erikson has emphasized, it influences the quality of the basic trust a child develops—the trust he has in others, in himself, and in the world in which he lives. It contributes to the child's self-esteem as a member of the male or female sex. It lays the foundations for trust in the reliability of collaboration with others and in the utility of communicating verbally as a means of solving problems. A person's physiological functioning can be and perhaps always is permanently influenced by the way in which the parental nurturing figures respond to his physiological needs.

From these brief comments it is apparent why so much attention has properly been paid to the parental nurturant activities and how profoundly they influence the development of a person; but they are but one aspect of

what a child requires from his parents and his family.

Structure

Let us now turn to consider the relationship between the dynamic organization of the family and the personality integration of its offspring. Although the family organization differs from one society to another and with social class and ethnic group within a society, it seems likely that the family everywhere follows certain organizational principles both because of its biological makeup and because of the specific functions it subserves. As noted above, the family members must find reciprocally interrelating roles or distortions in the personalities of one or more members will occur. The division of a family into two generations and two sexes lessens role conflicts and tends to provide an area free from conflict into which the immature child can develop, and directs him or her to grow into the proper gender identity, which forms the cornerstone of a stable ego identity. While all groups require unity of leadership, the family contains two leaders—the father and the mother—with different but interrelated functions that permit them to form the required coalition that permits unity of leadership. We may hazard that in order for the family to develop a structure that can properly direct the integration of its offspring, *the spouses must form a coalition as parents, maintain the boundaries between the generations, and adhere to their respective gender-linked roles.* These requirements may sound rather simple

until we explore their ramifications.

The Parental Coalition

As has been noted, all small groups require unity of leadership, but the family has a dual leadership. The mother, no matter how subjugated, is the expressive-affectional leader; the out his or her cardinal functions. The mother, father, the instrumental leader. A coalition between these leaders is necessary not only to provide unity of direction but also to afford each parent the support essential for carrying for example, can better delimit her erotic investment in the small child to maternal feelings when her sexual needs are being satisfied by her husband. The family is less likely to break up into dyads that create rivalries and jealousies if the parents form a unity in relating to their children; and, particularly, a child's tendency to possess one or the other parent for himself alone—the essence of the oedipal situation—is more readily overcome if the parental coalition is firm and the child's egocentric fantasies are frustrated and redirected to the reality that requires repression of such wishes. If the parents form a coalition both as parents and as a married couple, then the child, who is provided with adult models that treat one another as alter egos, each striving for the partner's satisfaction as well as for his own, is very likely to grow up valuing marriage as an institution that provides emotional satisfaction and security, thus gaining a long-range goal.

The child properly requires two parents: a parent of the same sex, with whom he can identify and who forms an object of identification to follow into adulthood, and a parent of the opposite sex, who serves as a basic love object and whose love and approval is sought by identifying with the parent of the same sex. However, a parent fills neither role effectively for a child if denigrated, despised, or treated as a nonentity, or even as an enemy, by the spouse. Parents who are irreconcilable in reality are likely to become irreconcilable introjects in the child, causing confused and contradictory internal directives. It is possible for parents to form a reasonable coalition for their children despite marital discord and to some extent even despite separation; they can agree about how children should be raised and support their spouses to the children as worthwhile persons and as good parents even if their ways and ideas differ.

A variety of difficulties can follow upon failures of the parental coalition. The growing child may invest his energy and attention in supporting one or the other parent or in seeking to bridge the gap between them, rather than utilizing his energies for his own development. Sometimes the child becomes a scapegoat with his problems magnified into the major source of dissent between the parents, and he comes to feel responsible for their difficulties. A child may willingly oblige and assume the role of villain in order to mask the parental discord, thereby retaining the two parents he needs. The child may also be caught in an impossible situation in which any attempt to please one

parent elicits rebuff or rejection from the other. When the parents fail to achieve a coalition, there are many ways in which the child becomes subject to conflicting motivations, directives, and standards that interfere with the development of a well-integrated personality.

The Generation Boundaries

The division of the nuclear family into two generations lessens the danger of role conflict and furnishes space free from competition with a parent into which the child can develop. The generational division is a major factor in providing structure to the family. The parents are the nurturing and educating generation and provide adult models and objects of identification for the child to emulate and internalize. The child requires the security of dependency to be able to utilize his energies in his own development, and his personality becomes stunted if he must emotionally support the parents he needs for security. A different type of affectional relationship exists between parents than between parent and child. However, the situation is complicated because of the intense relationship heightened by erogenous feelings that properly exists between the mother and each preoedipal child and by the slow differentiation of the child from his original symbiotic union with his mother. The generational division aids both mother and child to overcome the bond, as is essential to enable the child to find a proper place as a boy or girl member of the family and then to invest his energies in peer groups and

schooling, as well as in gaining his own identity. The generation boundaries can be breached by the parents in various ways, such as by the mother failing to establish boundaries between herself and a son; by the parent using a child to fill needs unsatisfied by a spouse; by the parent acting as a rival to a child; by the father seeking to be more of a child than a spouse. Incestuous and near incestuous relationships in which a parent overtly or covertly gains erotic gratification from a child form the most obvious disruptions of generation lines. When the child is used by one parent to fill needs unsatisfied by the other, the child can seek to widen the gap between his parents and insert himself into it; and by finding an essential place in completing a parent's life he need not—and perhaps cannot—turn to the extrafamilial world for self-completion. The resolution of the oedipal situation thus depends for its proper completion upon having a family in which the parents are primarily reliant upon one another or at least upon other adults. Further, if a parent feels excluded by a child, the child's fears of retribution and retaliation may not be simply projections of his own wishes to be rid of a parent, but may derive from the reality of having a jealous and hostile parent.

Confusions of the generation boundaries within the nuclear family together with the ensuing role conflicts can distort the child's development in a variety of ways, some of which have already been indicated. The child's proper place within the family is invaded; rivalry with parents absorbs energies and fosters internalized conflicts; a parent's dependency upon a

child occupies and preoccupies a child prematurely with problems of completing the life of another rather than with his own development. Aggressive and libidinal impulses directed toward the parents become heightened, rather than undergoing repression and gradual resolution, and are controlled only through strongly invested defensive mechanisms.

The Sex-Linked Roles

Security of gender identity is a cardinal factor in the achievement of a stable ego identity; and of all factors entering into the formation of personality characteristics, the child's sex is probably the most decisive. Confusions concerning sexual identity and dissatisfactions with one's sex can contribute to the etiology of many neuroses and character disorders as well as to perversions; and probably all schizophrenic patients are seriously confused concerning their sexual identity. A child does not attain proper sex-linked attributes simply by being born a boy or girl, but through gender role allocation that starts at birth and then develops through role assumptions and identifications as he grows older. The maintenance of appropriate gender-linked roles by the parents is one of the most significant factors in guiding the child's proper development as a boy or girl. Clear-cut reversals in the parents' sex-linked roles obviously distort the child's development, either when they are in the sexual sphere, as when a parent is overtly homosexual, or when they concern the divisions of tasks in maintaining the family. While it

is clear that a child whose father performs the mothering functions, both tangibly and emotionally, while the mother supports the family will usually gain a distorted image of masculinity and femininity, the common problem is usually more subtle: the inability of the mother to fill an expressive-affectional role or of the father to provide instrumental leadership for the family. As Parsons and Bales have pointed out, a cold and unyielding mother is more deleterious than a cold and unyielding father, whereas a weak and ineffectual father is more damaging than a weak and ineffectual mother." Still more explicitly, a cold and aloof mother may be more detrimental to a daughter who requires experience in childhood with a nurturant mother in order to attain feminine and maternal characteristics, whereas an ineffectual father may be more deleterious to a son who must overcome his initial identification with his mother, as well as his early dependency upon her, to gain security in his ability to provide for a wife and family. Although the sharing of role tasks has become a necessity in most contemporary families, which leads to some blurring of the parental roles, there is still a need for the parents to maintain their primary gender-linked roles and to support one another in them.

The child's identification with the parent of the same sex is likely to be seriously impeded when this parent is unacceptable to the other whose love the child seeks, a difficulty that can be heightened by the homosexual tendencies of a parent. The mother may be basically unacceptable to a father

with homosexual proclivities simply because she is a woman; and the daughter may respond by seeking to be boyish, by gaining the father's affection by being intellectual, or through some other means that do not threaten him by feminine appeal. If a mother, on the other hand, is consciously or unconsciously rivalrous with all men, her son may readily learn that masculinity will evoke rebuff from her, and fears of engulfment or castration by the mother become more realistic sources of anxiety than fears of retaliatory rejection or castration by the father.

Of course, other problems can create difficulties for a child in gaining a secure gender identity, such as when parents convey the wish that the boy had been born a girl or vice versa, or the need to avoid incestuous involvements; still, when parents adequately fill their own gender-linked roles and accept and support the spouse in his or her role, a general assurance of a proper outcome is provided.

The relationship between the family structure and the integration of the offspring's ego development is a topic that is only beginning to be studied. Still, a little consideration leads us to realize that the provision of proper models for identification, motivation toward the proper identification, security of sexual identity, the transition through the oedipal phase, the repression of incestuous tendencies before adolescence, and many other such matters are profoundly affected by the family's organization. Unless the

parents can form an adequate coalition, maintain proper boundaries between the generations, and provide appropriate gender role models by their behavior, conflicts and role distortions will interfere with the proper channeling of the child's drives, energies, and role learning.

The Family and Enculturation

The proper enculturation of the child within the family may be more properly divided into the process of socialization and the process of enculturation. Under socialization we may somewhat arbitrarily subsume how the child learns basic roles and institutions through interactions between family members; and enculturation concerns that which is transmitted symbolically from generation to generation rather than through societal transactions. However, there is considerable overlap, and the two functions cannot always be clearly distinguished.

The form and function of the family evolves with the culture and subserves the needs of the society of which it is a subsystem. The family is the first social system that the child knows, and simply by living in it he properly gains familiarity with the basic roles as they are carried out in the society in which he happens to live: the roles of parents and child, of boy and girl, of man and woman, of husband and wife. He also learns how these roles of the family members interact with the broader society. Whereas roles are

properly considered units of the social system rather than of the personality, they also are important in personality development through directing behavior to fit into roles and by giving cohesion to the personality functioning. Individuals generally do not learn patterns of living entirely on their own, but in many situations learn roles and then modify them to their specific individual needs.

The child also learns from his intrafamilial experiences about a variety of basic institutions and their values, such as the institutions of family, marriage, economic exchange, and so forth; and societal values are inculcated by identification with parents, superego formation, teaching, example, and interaction. The wish to participate in or avoid participating in an institution —such as marriage—can be a major motivating force in personality development. It is the function of the family to transmit to the offspring the prescribed, permitted, and proscribed values of the society and the acceptable and unacceptable means of achieving such goals. Within the family the child is involved in a multiplicity of social phenomena that permanently influence his development, such as the value of belonging to a mutually protective unit; the rewards of renouncing one's own wishes for the welfare of a collectivity; the acceptance of hierarchies of authority and the relationship between authority and responsibility. The family value systems, role definitions, and patterns of interrelationship enter into the child through the family behavior far more than through what he is taught or even what the

parents consciously appreciate.

The process of enculturation concerns the acquisition of the major techniques of adaptation that are not inherited genetically but that are assimilated as part of the cultural heritage that is a filtrate of the collective experiences of man's forebears. In a complex industrial and scientific society such as ours, the family obviously can transmit only the basic adaptive techniques to its offspring and must rely upon schools and other specialized institutions to teach many of the other instrumentalities of the culture.

The cultural heritage includes such tangible matters as agricultural techniques and food preferences, modes of housing and transportation, arts and games, as well as many less tangible matters such as status hierarchies, religious beliefs, ethical values and behavior that are accepted as divine commands or axiomatically as the only proper way of doing things and are defended by various taboos. The transmission of language is a primary factor in the inculcation of both techniques and values because the totality of the enculturation process depends so greatly upon it. After the first year of life the acquisition of almost all other instrumental techniques depends to a greater or lesser extent upon language; and the collaborative interaction with others, which is so critical to human adaptation, depends upon the use of a shared system of meanings. Indeed, the capacity to direct the self, to have any ego functioning at all, depends upon having verbal symbols with which one

constructs and internalizes a symbolic version of the world that one can manipulate in imaginative trial and error before committing oneself to irrevocable action. As virtually all intact children learn to speak, we are apt to overlook the complexities of the process of learning language as well as its central importance to ego functioning. It required the linguistic anthropological studies of Sapir and Whorf to illuminate how profoundly the specific language that a person utilizes influences how he perceives, thinks, and experiences. The studies of schizophrenic patients and their parents illustrated how greatly faulty and distorted language usage can affect personality development and functioning. The inculcation of a solid foundation in the language of the culture is among the most crucial tasks carried out by the family.

Speaking very broadly, the child learns language through attempting to solve problems. Meanings are established rapidly or slowly, with clarity or vagueness, in accord with how effectively and consistently the proper usage of words gains objectives for the child. The process depends upon reciprocal interaction between the child and his tutors, the consistency among his teachers, the cues they provide, the words to which they respond or remain oblivious, the meanings that they reward consistently or sporadically, or that they indicate are useless, ineffectual, undesirable, repugnant, or punishable. Many other factors are also involved in the child's attainment of language, but it is clear that the family plays a very important part in the process. The

categorizing of experiences through the abstraction of common attributes, the labeling of categories by words, and the sharpening of the meaning of words by grasping the critical attributes designated by the word are essential for both ego development and proper ego functioning.

In contrast to the commonly accepted dictum expressed by Hartmann, the infant is not born adapted to survive in an average, expectable environment. The range of environments in which he is physiologically capable of surviving are relatively limited, but every viable society develops a set of instrumental techniques and institutions that take the infant's essential needs into account and modify the environment to the child's capacities. Then, very largely through the use of language, the child learns the culture's techniques of adaptation more or less adequately, and gains an ability to delay the gratification of basic drives, to internalize parental attributes, directives, and teachings, and to be motivated by future security as well as by drive impulsions. Further, the world in which he lives, the behavior of others, and his own needs gain some degree of order and predictability through the categories provided by the language.

Upon consideration it seems apparent that the parental styles of behaving, thinking, and communicating, as well as their specific patterns of defenses, are critical factors in the development of various personality traits in their children, both through direct example and the internalization of such

traits by the children as well as through the reactions that such styles produce in the child. When Bateson and Jackson formulated their double-bind hypothesis of schizophrenia; when Lidz, Fleck, et al. noted how schizophrenic patients had been taught to misperceive, to deny the obvious, to be suspicious of outsiders; and when Wynne and Singer documented that virtually all schizophrenic patients have parents who have either amorphous or fragmented styles of communicating, a new dimension was added to the study of personality development as well as to the study of psychopathology. In the study of the obsessional character, for example, instead of focusing primarily upon what occurred in the patient's "anal" phase of development, we begin to note that the parents of such persons are usually obsessional themselves, unable to tolerate direct expressions of hostility in themselves or in their children. They are very likely to teach the use of isolation, undoing, and reaction formation as a defense against the expression of hostility both through their own example and through what they approve and disapprove in their children.

Such obsessional parents are likely to use rigid bowel training and to limit the young child's autonomy and thus foster ambivalence, stubbornness, shame, and undoing defenses in many ways other than simply through the way they direct the child's bowel training.

Conclusions

Personality development cannot be properly studied or understood abstracted from the family matrix in which it takes place. The major foci of attention—the childrearing techniques and the emotional quality of the nurturant care provided the child—while clearly very important do not encompass the topic. The child's development into an integrated individual is guided by the dynamic organization of his family, which channels his drives and directs him into proper gender and generation roles. The child must grow into and internalize the institutions and roles of the society as well as identify with persons who themselves have assimilated the culture. The child acquires characteristics through identification but also by reactions to parental figures and through finding reciprocal roles with them. His appreciation of the worth and meaning of both social roles and institutions is markedly affected by the manner in which his parents fill their roles, relate to one another, and behave in other contexts. The perceived reliability of the verbal tools that are necessary for collaboration with others and for thinking and self-direction depend greatly upon the tutelage within the family and on the parents' styles of communicating. In the study of personality development and in our search for proper guidelines to help provide stable emotional development, the emphasis upon what parents should or should not do to the child, for the child, and with the child in each phase of his development has often led to neglect of other more significant familial influences. Who the parents are; how they behave and communicate; how they relate to one another as well as

to the child; and what sort of family they create including that intangible factor, the atmosphere of the home, are of paramount importance. Numerous sources of deviant personality development open before us when we consider the implications of the approach to personality development presented in this chapter.

Chapter 12

Infant Development

David E. Schecter

The frame of reference of the behavioral sciences, including psychiatry, is increasingly expanding to include psychohistorical and intergenerational considerations, especially with the realization that the needs of child, youth, and adult are, to a large degree, mutually interdependent—each group having needs to confirm and be confirmed by the other. We mean to emphasize in our discussion of infancy—approximately the first fifteen months of life—the reciprocal relatedness between child and caretaker, whether the caretaker is parent, professional, or extended family. With new possibilities in societal and childrearing structures (the daycare center, the kibbutz, the commune), it is more important than ever to understand the nature of the infant and his dependency on his caretakers, even if the child were to be conceived in a test tube. For practical purposes we will assume that the family—or a variant thereof—is still viable and still a rather universal matrix in which children are reared, notwithstanding the influences of other institutions.[1] Traditional parental roles—and the security that comes with these roles—have already

broken down to varying degree in the Western nuclear family, with an ensuing search for new forms of childrearing that may be adaptive to a relatively unknown and unpredictable future world. Hence the widespread phenomenon of acute and chronic parental doubting concerning a range of problems connected with child and adolescent rearing, with life style, and with basic value orientation.

Although traditionally concerned with alleviating symptoms and altering deviant behavior, psychiatry has moved into community concerns, recognizing its potential contribution to the fostering of mental and emotional well-being as well as to the prevention and treatment of suffering and destructive behavior among the people of the world. If we can understand the nature of human development in its various sociocultural forms, we increase the possibilities of knowing the conditions under which "healthy" development can be facilitated. Since the human organism has a wide range of adaptability, the issues of "health" and adaptation are closely related. "Adaptation to what" involves matters of human value's and goes beyond the usual boundaries defined by a narrow scientific approach that attempts to remain value-free or— more accurately—value-blind. For example, if a family or a society's goal is to encourage self- control in a child, there are many routes toward this behavioral end. One end of the spectrum would rely on providing a milieu that encourages self-control by example and encouragement as well as by a clear setting of limits; the other direction

would make use of techniques weighing most heavily on fear, coercion, or shaming. Although the surface behaviors in each instance may have a similar appearance, the different psychological structures involved in these examples would have completely different implications for the child's total development and for the social relations of which he becomes a part.

The Birth of a Family

The biological helplessness of the infant demands nurturance from caretakers who have a high stake in the infant's growth and development. Traditionally the family has been entrusted with the functions of fostering the child's biological, social, and cultural development. This implies that from the time of conception parents will try to influence the new organism in directions largely dictated by their personal and socially shared values. However, the freedom to nurture optimally a completely dependent fetus and infant depends a good deal on the level of psychological maturity attained by the parents.

Parenthood can be regarded as a developmental phase, incorporating several substages, with stage-specific tasks, stresses, and opportunities for growth. The young adult usually comes to parenthood while he is still undergoing a series of individuation experiences in which he has attempted to liberate himself psychologically from his family of origin through an

intense inner struggle to establish his—or her—own sense of identity. Simultaneously a need develops for a relatively enduring, intimate relationship, which often involves the formation of a new social unit, a "couple."[2] In such a setting we can observe fluctuations from states of relative psychological separateness to states of greater fusion or loosening of ego boundaries. The latter is experienced not only during sexual excitement and orgasm but in the not infrequent expectation that the one partner have *identical* wishes, tastes, and values as the other. With the relative sense of exclusive possessiveness seen in some new couples, there are temptations toward regressions, including increased dependency and fusion that evoke affects associated with earlier parent-child experiences. In part this accounts for the cyclical moving toward and away from one another in any intimate relationship.

Against this background of relatively exclusive couplehood, a pregnancy can potentially come to signify an intrusion into the new unit. At the very least, even when the pregnancy and newborn are consciously and unconsciously welcomed, there will be a marked disequilibrium and need for new homeostasis in the new family unit. The- capacity for the dyad to grow into a relatively harmonious triad is one of the essential developmental tasks of parenthood, the outcome of which will have enormous impact on the child's and the family's development.

We know from clinical as well as from direct family observations that pregnancy and infancy set up new strains in both parents. Aside from the demandingness of the new infant, there is a shift of emotional investment (cathexis) in the mother—especially after quickening—when she becomes aware of a new being that is inside and part of her. If the husband needs his wife at the same level of intensity as in prepregnancy, he may experience some deprivation, which can be overcome—if he is mature enough—especially with the feeling of a new pride in his role as father. In families we have studied in weekly observation for the first two years of life, we have noted in some fathers clear signs of deprivation, jealousy, and feelings of being excluded.[3]

Since there tends to be a social idealization of infancy, demanding an unambivalently blissful family atmosphere into which the infant is supposed to be received, ambivalent affects are generally suppressed or repressed, and investigation of these feelings has been hampered by a sense of taboo surrounding this issue. Also, from clinical experience with parents in various settings, one would suspect that there may be a widespread incidence of new families suffering in a quiet spirit of desperation. [4]

Although discussion of father's role is often absent in consideration of early family development, such considerations are manifest in mythology—probably indicating the rather universal nature of these problems. There is a

whole other side to the Oedipus-type myths that Freud did not emphasize. This perspective involves predictions that the newborn (son) would preempt and perhaps kill the father of the new family. This prophecy of the Delphic oracle provoked Laius and Jacosta to attempt infanticide by tying Oedipus's feet and leaving him to die in the fields in order to save their marriage and kingdom.[5]

The observations that a father may feel that his wife has "the inside track" with their son and that the mother feels despairing about her lack of abundance to provide for both child and husband should not obscure the fact that these conflicts are often resolved in a positive direction; the couple transcends its former structure to make room for—and, indeed, feel enriched by—the common pleasures and tasks involved in the child's growth. With this capacity of the parent to move from exclusive couplehood to a communal triad, there develops a sense of growing into generative adulthood (Erikson) in which one's potency and surplus vitality is expressed in the sharing of the care and concern for another whose importance is experienced as at least equal to one's own.

Parent-Child Developmental Fit: Individual Differences and Sociocultural Factors

The many variables that are involved in the adequate growth of a family include the character and maturity of the parents, the constitutional

difficulties and demands posed by a newborn, and his "match" with what his parents—and by implication their sociocultural group—can tolerate and respond to. The work of Bridger, Birns, Chess, Thomas, *et al.,* and Escalona reveals the early appearance of individual differences in infantile reactivity and temperament and the complex relation of these factors to parental expectations and responsiveness. The matter of parental expectations and hopes for their infant is of paramount importance in determining how the parents will evaluate the infant's progress and their own worth and "goodness" as parents.[6]

Our own observations of infant-parent interaction impressed us with the intensity of parental expectation and hope for their infant's achievements in accordance with a kind of idealized developmental schedule. If one of these goals—for example, to be independent, to play by himself, to reach and grasp —was not achieved by a certain age, there could ensue a sense of disappointment and failure leading to blame of self, child or spouse, and to mounting family tensions, whose origins the parents would soon become unaware of in the complex mesh of secondary interpersonal stress. We observed a two-month-old infant with colic shrieking for relief, but when his mother carried him "too long" in order to soothe him she was accused by her husband— and eventually accused herself—of "spoiling" the child. The fear of spoiling the infant proved quite prominent in a number of parents and was one of the sources of doubt and dulling of spontaneity in the parents'

attitudes toward their child. Behind the issue of spoiling is a fear of inducing overdependence and an omnipotence of will in the infant. At times these matters could be amusing, but they also signified a damaging form of patterning when many spontaneous behaviors in a very young infant were assigned the significance of willfulness and defiance.[7] Thus, a three-month-old infant was spanked by her father because she "refused" to go to sleep; on another occasion, using unfamiliar strident vocal tones and threatening facial gestures, her mother severely reprimanded her when the infant's protruding of her tongue was interpreted as a sign of disrespect. A further example of the fear of giving "too much attention" was seen in the mother's decision to withhold bodily contact with the baby by propping the bottle during most feedings. We must emphasize that although these were not the most sensitive of parents, they were also not too unrepresentative in many respects of what we saw in lower-class and lower-middle-class homes.[8]

Messiness and *dirtiness* in connection with feeding proved to be another source of maternal anxiety and consequent scolding or punishment in the early months of life. In this way important early autonomy striving such as self-feeding by finger, spoon, or cup can be discouraged by a mother whose sensitivity to messing or whose need to control overrides the child's readiness for certain masteries. Spock has written about how critical the period of five to six months is for the development of increasing autonomy and self-reliance through the potential mastery of cup feeding at this time.

We saw the beginnings of the "power struggle" from the parents' side much earlier than the classic autonomy phase usually ascribed to the infant in his second and third year of life. Even though we were impressed with the observations of how maternal attitudes and behaviors were influenced by the infant's behavior, we were even more impressed with the limitations of this proposition.[9] Parental character—in some aspects individually unique, but in its basic dimensions determined by sociocultural patterning—was seen to exert a powerful influence on the threshold, intensity, quality, and flexibility of parental response in relation to the infant's behavior, including the developmental changes in his behavior organization.

Despite the warps of development that can follow from inappropriate parental standards and expectations, it is clear that standards are—in varying degree of flexibility—common to all societies. Parental hopes for their offspring are universal and have been expressed in the form of the messianic ideal; this theme runs through various religious, mythological, and artistic motifs throughout history. The intense affective investment in the child increases the chances of species and individual survival as well as cultural continuity, even though it lays the groundwork for potential disappointment, disillusion, blame, and resentment in family relationships. Even so, despite the inevitability of parental inner conflict and guilt in Western culture,[10] one can observe parents within this framework who show remarkable sensitivity and skill in facilitating and enabling opportunities for the infant's movement

toward an optimal balance of interdependence and autonomy.

Development of the Human Bond

Of all the developments in the first year of life, that of the human bond between the infant and his caretaker—or caretakers—is probably the most fateful for his future life. We have presumed that the unfolding of the child's subsequent interpersonal relationships derives heavily from the patterning of the first social relationships. I have avoided the use of the word "mother" here, lest we assume that it is only with one's actual mother that the primary social bonds can be formed. Originally psychological, including psychoanalytic, formulations concerning the mother-child relationship were largely reconstructive or theoretical. Only in recent years have there been direct and specific kinds of researches to help elucidate the exact nature of the unfolding of the first human relationship.

There are several types of theories concerning the process by which the child becomes socially related. One type is concerned with the formation of the social bond, largely through secondary psychological dependency deriving from repeated cycles of gratification through the reduction of need-tension, primarily oral. This type of theory—largely involving the precepts of social learning—is in essence the one formulated by Freud, who properly emphasized the helpless nature of the newborn infant whose survival

depends on the ministrations and need gratifications by his caretaker. However, Freud also postulated a primary instinctual sucking drive that was anaclitic in its nature since it "leaned on" what he then referred to as the self-preservative ego instincts. The object of the sucking drive was seen as the breast—the social bond to mother being developed largely through the secondary psychological dependency described above.

Bowlby and others (Balint, Fairbairn) have emphasized a primary object seeking tendency in the infant from the time of birth. Bowlby postulates mechanisms—derived from ethological models—by which the primary attachment to the mother is mediated. These mechanisms, referred to as "component instinctual responses," are made up of species-specific behavior patterns, determined by heredity and emerging within specific developmental periods during the first years of life. The five "instinctual responses" suggested consist of sucking, clinging, following behavior (both visual and locomotor), crying, and smiling. Bowlby himself stresses that his theoretical model was intended to retain but update Freud's original schema of component instincts. From an evolutionary point of view, Bowlby considered the instinctual responses as having evolved with the adaptive function of eliciting nurturing behavior on the part of the mother. As Yarrow points out, a third theoretical framework, central to psychoanalytic theory—that of "object relationships"—is probably the broadest one, with a clearly developmental orientation that takes into account different kinds of social

responses at different developmental stages. The controversy that has ensued between primary and secondary attachments (Bowlby) is largely spurious because in human development it is, at least at the present time, practically impossible to separate out the primarily innate from the experiential since early infantile experience tends to become organized and patterned, and presumably immediately begins to have its effects on later development. Nevertheless, this does not rule out the fact that certain maturations must occur before certain kinds of experience can be undergone and organized by the infant. Many ethologists have largely abandoned the idea of an entirely innate origin of instinct-based behavior; Schneirla, for example, in his studies of cats, has shown the influence of early learning in complex mother-kitten interaction on the eventual "bio-psychological" mother-child relationship.

Oral and Feeding Behavior

That the oral and feeding experience of the infant constitutes one of the important basic roots of social attachment is not in question. However, historically, because of the obvious power of the sucking drive and its crucial connection with satisfaction of hunger and with survival itself, it was seen as the dominating experience that mediated the attachment to the mother. Indeed, the whole period of infancy was conceptualized as "the oral phase" of libidinal development. In nature, however, the oral experience involves other sensory modalities such as tactile, auditory, visual, and olfactory stimulation.

Nevertheless, even with the exciting new discoveries of the importance of the visual modality—described elsewhere in this chapter—we should not underestimate the critical quality of the feeding experience. We know, for example, that mothers who respond to their child's cry and discomfort almost exclusively by offering the breast or the bottle condition their infants in such a way that oral craving is experienced and oral satisfaction may be more usually sought out when distress is felt.[11]

A number of authors, including Erikson, Sullivan, and Brody, have emphasized the building up of a quality of interpersonal mutuality through the feeding experience; a number of fine manipulations and adaptations must be made by both partners in order to achieve a reciprocally gratifying feeding experience.

The significance of *contact comfort* and *tactile gratification* early in the life of the infant is dramatically demonstrated when the crying infant quiets upon being picked up and held, at first by any caretaker, but after a few months usually by the preferred mother. We assume that tactile, pressure, thermal, olfactory, and kinesthetic stimulation (Mason) have an ongoing impact on infantile experience. Harlow's work dramatized the importance of tactile experience in infant macaques, who apparently preferred artificial terry cloth mother surrogates to wire mesh lactating surrogates. Although Harlow had reason to conclude that contact comfort was more important

than feeding as an antecedent to social attachment, I believe this is a false kind of distinction because this type of competitive choice between these two particular modalities does not occur in nature as it does in Harlow's experiments. Also, in general, any inferences to humans from infrahuman species carry a risk, although the relevance of such inferences for early infantile development may be of a somewhat higher order. There is, however, initial evidence that experimental stimulation of institutional infants—exclusively in the tactile modality—contributes to significant developmental gains.

The evidence for the existence of important individual differences in the intensity of oral drive and the pleasure experienced in close physical contact is rather impressive. For example, Schaffer and Emerson studied a group of infants who could be differentiated into "cuddlers" and "noncuddlers." The authors concluded that the noncuddlers were not suffering primarily from maternal contact deprivation; rather, as a group, they were more advanced and more active motorically, and at the same time they tended to resist restraint of movement, including the restraint consequent to close physical contact.[12]

Visual and Auditory Modalities

In recent years research has revealed that the visual apparatus is

relatively ready to function soon after birth. Tauber demonstrated the optokinetic nystagmus reaction movement in newborns; Wolff and White observed visual pursuit of objects with conjugate eye movements in three to four day olds; Fantz described more prolonged visual fixation upon more complex visual patterns as against simpler ones in the early days and weeks of infancy.

The normal face is similarly "preferred" to comparable head shapes with scrambled features in infants from one to six months. Spitz and Ahrens in separate, very detailed analyses were able to demonstrate that the infant appeared to smile in response to a "sign gestalt," at first centering around the two eyes and later becoming more differentiated to include the mouth. A number of observers, including Wolff and Robson, have noted the development of preferential visual fixation upon, and following of, the human face from the early weeks of life.[13]

Wolff, through careful observation and experimentation, discovered that as early as the third week in the infant's life the specifically human stimulus of a high-pitched voice elicits a smile more consistently than any other stimulus at that time. The voice also served to reduce the infant's fussiness as well as evoke a smile. Our own experience, as well as that of others, indicates that a most effective way of evoking a smile in an infant from the second month onward is by a "social approach," consisting of a smiling,

nodding face, with accompanying musical vocalizations—that is, with the cumulative potency of various modalities.

Research observations would point to the probability that the infant is equipped innately with the capacity for a smiling response, a capacity that is evoked by a set of key "releaser" stimulus configurations—such as the human face gestalt—which become effective at certain phases of development. This point of view clearly does not exclude a complementary one that regards the smiling response, once elicited, as being immediately open to various influences of learning, including conditioning and the increasing emotional investment in the recognition of familiar persons.[14]

Social and Playful Interaction

There is by now a mounting volume of evidence[15] that the crucial variables in determining the outcome of social responsiveness in the potentially healthy infant are the patterned social stimulations and responsiveness of the significant persons in the environment. Without adequate social (including perceptual) stimulation—as, for example, in blind and institutionalized infants—deficits develop in emotional and social relationships, in language, in abstract thinking, and in inner controls. Barring social traumata and deprivation of varying degree, nature and culture seem to guarantee reciprocal responsiveness by the fact that healthy adults, especially

those who are intensely invested in their infants, find the infant's smiles and vocalizations irresistible; they apparently must respond unless the caretakers are particularly depressed or disturbed.

By five to seven months the infant who is being enjoyed by his parents spends a good part of his day in social interactions involving mutual regard, sometimes with intense eye-to-eye contact, and mutual smiling and vocalizations; these may include tactile and kinesthetic stimulations, modalities that are all combined in various ongoing patterns of interaction. Many of these patterned exchanges become idiosyncratically personal to the mother-infant couple, while others represent traditional social play, such as presemantic vocal "conversations" and repetitive social approaches and responses, which may involve nuzzling, jiggling or jouncing, postural games of lifting and lowering, "upside down" and "airplane" and—most dramatically— the game of peekaboo. [16]

By the end of the first half year of life, mother and infant have developed important patterns of social interaction. In some couples the baby is given maximal opportunity to actively respond and initiate; in others he is coerced into the position of a relatively passive recipient of stimulation that may excite him to the point of painful stress. Some of the variables involved in a systematic study of the patterns of reciprocity include: the infant's and mother's sensitivity and activity levels, their initiatory tendencies, mother's

need to dominate rather than facilitate her infant, the nature of her personification of her infant (is he to be docile or actively initiatory), mother's anxiety level, her fear of "spoiling" the child through play, and so on. A prominent feature of maternal style includes the mother's *capacity to enjoy and respond* to her infant's activity, including his developmental progressions. The maternal variables are stressed here for the moment, since social reciprocity in the infant is given largely as a potentiality and, to a great degree, must be induced and sustained by the significant adults.

In the earliest months of life, the mother responds to physiologically based needs (hunger, cold, sleep). She functions as a protector from excessive inner and outer stimulation as well as a provider of perceptual stimulation. As the infant develops a repertoire of reciprocal playful experiences, he comes to anticipate and learn that he can evoke a social response even when he is not hungry, cold, wet, or in pain. *With this realization develops a new sense of "social potency" and trust that is qualitatively different from urgent need tension relief.* The child can now obtain not only reduction of tension but also positively stimulating and playful patterns of response in relation to a human partner, as well as with objects.[17]

Social playfulness, perhaps more than any other modality, constitutes a remarkably easy vehicle for the mutual exchange of affectionate and exuberant affects. Since play is characterized by the quality of continuing

improvisation and hence by the availability of novel elements of experience, it operates as a powerful motivator of learning. As Piaget has demonstrated, the development of learning structures proceeds by the assimilation of novel inputs in the infant's experience, followed by appropriate accommodations. *Reciprocal play* appears to involve the utmost of focal attention and absorption of the two partners—a kind of sacred ritual that one dare not intrude upon. When the caretaker—adult or adolescent—experiences this with the infant, the latter gains a new degree of human status, now being perceived as a psychological and social as well as physiological being. At the same time a new kind of parental pride appears; the mother's self-esteem is validated by her feeling that she has succeeded in helping her baby become socially human. It is at this point in development that fathers—often for the first time—experience themselves as a meaningful part of the infant-parent relationship. Playfulness requires special conditions, for instance, an appropriate level of stimulation and an absence of coercion and domination. In this sense we can see that mutual playfulness is a model of freedom and spontaneity in human relatedness. It helps prepare the individual and group for communication, language, and collaboration and provides a means for overcoming destructiveness through playful aggression.[18]

The internalization of "good" reciprocal relationships comes to be organized as part of "good me" and "good mother" and contributes eventually to the sense of one's self-esteem. With the confidence that he can evoke a

response, the child is freed to "be alone in the presence of mother," as Winnicott states it, a phase that prepares him for separations from mother's physical presence for longer periods without undue anxiety. This is a crucial step in the development of the infant's autonomy. If parents are depleted emotionally for any reason (depression, social deprivation, and hardship), one of the first qualities of a relationship to fall away is playfulness since this depends on a surplus of emotional well-being. When we speak of emotional deprivation in infancy, this refers not only to the gross kinds of deprivation seen in such situations as institutionalization and obvious parental psychopathology but also to the more subtle quality of the interaction between parent and child.[19] Moreover, we must keep in mind not only the quality of parenting but also the individual characteristics of the infant that determine the nature of the stimulation he requires; for example, a passive, low-energy infant who cannot actively send out signals that will bring response is more in need of stimulation that is initiated by the parents than a more active, self-initiatory infant.

Developmental Stages of Social Attachment

When looked at closely the development of social attachment can be described as a complex series of steps in achieving a meaningful special relationship to other persons. Because of different rates of development and the diversity of research definitions and criteria in studying social

attachment, we cannot expect to find a fixed age at which a given level of attachment is achieved. Furthermore, the observer can only use behavioral reactions and from them draw inferences about qualities and levels of social attachment. The infant is in no position to verify or contradict these inferences.

What is the significance to psychiatry of detailed developmental studies of social attachment? It is nothing less than the foundation of all human relatedness and of personality development. To study carefully the different levels of social relationship allows the student of human behavior to recognize, for example, at what level of relatedness a particular person—or group—may be operating at a given time and also at what level a person may have been arrested in his development. Such knowledge will allow for a reconstructive viewpoint in attempts at individual and social change. If we know there tends to be a relatively invariant sequence of stages A, B, C, D in the formation of a human attachment, we will not expect or demand D level behavior if step C has never been achieved. This developmental viewpoint alters the conception of individual and social therapies that have been modeled largely on the issue of conflict, without too much regard for the structural elements of personality that are needed for a certain level of interpersonal behavior and conflict. For a person who has not achieved the capacity for close specific social attachment in infancy, one would not expect to find the higher level oedipal-type conflicts that already presume a capacity

for specific social attachment.

From the work of a number of investigators, including Spitz, Benjamin, Schaffer and Emerson, and Yarrow we can summarize the various stages by which social attachment between infant and mother is achieved during infancy.

1. *Undifferentiated presocial phase.* The infant in the early days or weeks of his life may fail to discriminate social and nonsocial objects.

2. *Indiscriminate social responsiveness.* The infant now discriminates social and nonsocial objects but responds without apparent discrimination among various social objects. It is at this stage that Spitz's comment applies: the mother is a function and not yet a face.

3. *Selective responsiveness* to familiar versus unfamiliar people. One type of selective responsiveness involves the recognition of the mother as revealed by a series of behavioral signs, including selective concentration on the mother, excitement and approach movements at the sight of her, as well as differential crying, smiling, and vocalization. Mother is no longer merely a function; she has a face.

There seems to be agreement that perceptual discrimination precedes the possibility of recognition of the mother as a specific person, and that recognition, in turn, is a prerequisite for stage 4.

4. *Specific social attachment.* According to Schaffer and Emerson,[20] there was a peak of specific social attachment at 10 to 11 months, followed by a slow decline. At 18 months there seemed to be an increase in the attachment curve, reaching its previous peak that had been found at 10 months. It is likely that the development of specific attachments and expectations toward the mother or other significant persons depends on certain perceptual and cognitive developments, including the beginning concept of "object permanence" (Piaget)—the mental representation of objects when they are outside the infant's immediate perceptual field. It is important to note that in Piaget's experiments on object permanence, the child*begins* to retain an image of the disappeared object and seeks it out under a napkin beginning around nine months of age, completing the mastery of the complexities of object permanence around 18 months. In nature, of course, one cannot separate the cognitive from the affective-social bonds; these dimensions are abstracted from a unified gestalt experience in the infant's life.

5. *The Confidence relationship.* This higher level of interpersonal relationship—derived by Yarrow from Benedek—involves the development of specific expectations toward the mother and overlaps significantly with Erik- son's concept of basic trust. However, since complex inferences about the meaning of behavior are necessary, the development of behavioral criteria for "confidence" or "trust" is extremely difficult. Yarrow chose, as one criterion, "the expectation of soothing when in distress," and he found that about half the infants

had developed this relationship of confidence to the mother by age three months and 56 per cent at age six months. (His study did not go beyond eight months.) Yarrow concluded that the development of confidence in the mother is not simply a maturationally determined development, but undoubtedly influenced by many environmental as well as idiosyncratic factors, including the patterns of maternal care, "such as the depth of the relationship, the consistency with which mother responds to the child as well as the general level of predictability of the environment based on recurring and predictable sequences of gratification."

From our own and others' observations of infants, we know that the increasing capacity to anticipate and wait for specific responses in the mother increases with age in a good relationship and, indeed, is an early sign of what is meant psychoanalytically by the concept of object constancy.

6. *Object constancy.* As Fraiberg has indicated, the criteria for achievement of object constancy vary a great deal with different authors, so that its achievement is placed at ages ranging from eight months until after the second year. In any case what is meant by this concept is that not only can the child discriminate and selectively value his mother but also he has begun to represent her mentally with qualities of increasing permanence and objectivity. Even in the face of frustration or cruelty or during a limited absence, the mother usually continues to be preferred and central to the child's life.

The evidence for achievement of object constancy in the psychoanalytic sense—in contrast to Piaget's purely cognitive concept of "object permanence"—is not on certain grounds empirically, but there are behaviors that would indicate the mother is represented mentally and invested with intense affect.[21]

The child, for example, will call for his mother by whatever "call sounds" he has developed to summon her to himself; when she is absent he will verbally refer to her or to her possessions and he will miss her grievingly. Even nonverbally, his beginning dramatic play indicates that he is developing the capacity to mentally represent himself and mother in a mobile symbolic act—for instance, when he places a doll to sleep during a play sequence. His mental operations have progressed beyond immediate imitation to what Piaget calls deferred imitation, and then to the formation of more lasting identifications with the mother. Evidence for these identifications are revealed in the toddler's play, whose content is in part concerned with parental attitudes and the roles of provider, helper, protector, and comforter (Schecter).

During the second year of life, the child's very special relationship to the mother, in a nuclear family, becomes increasingly complex and elaborated. The child shares his inner and outer world with his mother, verbalizing fantasies and fears, bringing her objects, naming them, and expecting an

affirming response from her. Even as the child increasingly individuates, he becomes capable of sharing a rather private world—a shared "mythology"—in the sense that there are idiosyncratic words for special objects; there are frequent recapitulations of memory experiences that both have shared together; and there's repetitive playing of games that are bodily, kinesthetic, verbal, musical, that is, play involving almost every modality. This is probably the period of bliss frequently represented in Renaissance art in the idealized version of mother and cherub—for many, a period to remain imbued with paradisic feeling.

Intensity and Breadth of Social Attachments

Schaffer and Emerson found that factors increasing the seeking of proximity to the mother include:

1. Pain, teething, illness, fatigue, and fear

2. A period of the mother's absence (which corroborates Bowlby's finding of greater clinging and demandingness after separation)

3. The habituation effect of a period of great stimulation such as occurs during the visit of a doting relative

4. When the infant enters a strange environment

All these factors are relevant to later development, including adulthood. We have already indicated the importance of understanding the factors that contribute to a predisposition to habituation and addictions of various kinds. More intensive longitudinal study of habituation levels in infancy and childhood could test their correlation with personality outcomes characterized by needs for strong stimulation and input of various kinds.

An important topic under discussion currently is that of the "breadth of attachments" of infants to significant persons. We can infer from the work of Schaffer and Emerson—as well as from observations of societies with multiple child caretakers—that a single person is not necessarily the first step in forming a specific social attachment. In Schaffer and Emerson's research almost one-third of the infants showed attachments to multiple persons in the phase of specific social attachments. However, their work does not disprove the possibility that intensive early mothering may have been a prerequisite to the broadening of specific attachment. In most cases (62 per cent) fathers were found to be specific objects of social attachment after the onset of the phase of specific attachment. In fact, for 4 per cent of the infants in their sample, the father was the only specific object of attachment at seven months. Hence we find the possibility of a "hierarchy of object persons," the most intense attachment being shown to the principal object person, who is not necessarily the mother.[22]

Origins of Infantile Anxiety

As Benjamin points out, a satisfactory design to tease out the relative contributions of hereditary, intrauterine, birth, and early postnatal factors has been impossible to actualize until now. Even though Greenacre re-presented Rank's idea of the birth trauma in a far more sophisticated form, it is still useful mainly as a concept of a single variable in a predisposition to anxiety. More recently the possibility of learning from experience in the early weeks of life adds a new variable both to the predisposition and to the idea of actual anlagen to anxiety experience. So much depends on how anxiety is defined in infancy that it may be more fruitful to describe the various critical periods of its development— leaving open the theoretical question of what constitutes anxiety,[23] in contrast to infantile fear or undifferentiated negative affect, which we see, for example, in reaction to overstimulation of various kinds.

Benjamin's observations led him to postulate a "critical period" at age three to four weeks when a rapid rate of neurophysiological maturation accounts for an increased capacity to register internal and external stimulation. Benjamin hypothesized that in the ensuing weeks the quality of mothering in protecting the infant from this new source of stimulation might contribute to the subsequent predisposition to anxiety. The relatively undifferentiated negative affect expressed upon being left alone can be seen as a consequence of a form of habituation to a certain level and quality of

stimulation rather than to the experience of loss of a truly discriminated mother.[24]

Before the appearance of infantile stranger anxiety proper, Benjamin postulates an innate fear of the strange as is seen in the two- to four-month-old infant's negative reaction to strange objects or sounds—or to being handled in an unaccustomed manner. An apprehensive response may also be aroused in the young infant by altering an anticipated gestalt pattern through the addition of unfamiliar elements or by the omission of some apparently crucial familiar element. We have noted, for example, that some infants respond with a look of apprehension at the appearance of a smiling, nodding adult face that is presented without the accustomed vocal accompaniment. When vocalizations are added the infant relaxes and smiles, giving the impression of closure of the anticipated familiar gestalt.[25] In a similar vein a humming or falsetto voice lacking visual presentation of the human face could produce fearful reactions that disappeared once the face was brought into view. The infant may respond with apprehension to a variety of alterations of the facial gestalt, such as the placing of pads over the eyes, the forbidding expression with vertical—in contrast to horizontal—forehead creasing, or changes in the mother's appearance when she wears a new hat, glasses, or hair curlers. However, it is the expression around the adult's eyes that seems to have particular significance for the infant; this fits with Wolff's observation that the infant tends to search out the eye area and make eye-to-eye contact

before smiling at the presentation of a face.[26] These signs of increasing perceptual discrimination predate and constitute a necessary precondition for the development of infantile stranger anxiety.

The infantile stranger reaction has been properly distinguished from separation anxiety by Benjamin. Freud and Spitz considered the "eight-month anxiety" in reaction to the stranger to be based on the same dynamic found in separation anxiety, namely, the fear of object loss. Benjamin found that although stranger and separation anxieties are related dynamically and even positively correlate statistically, nevertheless, there are babies showing high levels of separation anxiety but low stranger anxiety and vice versa. Stranger anxiety can occur whether or not the mother is present, whereas separation reactions occur in the absence of the mother whether or not anyone else is present. Moreover, the average and peak time of onset are different for each type of anxiety, occurring somewhat earlier for stranger anxiety. [27]Phenomenologically the reaction to strangers runs a gamut from no apparent reaction, visual concentration without apparent affect, reserved friendliness after initial wariness to sobering with mild apprehension, inhibition of motor behavior ("freezing"), aversion of visual gaze, clinging, withdrawal, active protest, screaming, and paniclike behavior.

Aside from its own intrinsic significance, this description of the reaction to strangers is also offered to help elucidate another poorly understood form

of anxiety central to H. S. Sullivan's theory of interpersonal relations— that is, the anxiety induced in the infant by the anxiety of the mothering one through as yet unknown mechanisms that Sullivan referred to as "empathic linkage." Various observers have noted, for example, that a baby would suffer feeding disturbances when fed by mothers who were high-strung and excitable while accepting the same formula from another feeder. It is our hypothesis that when the mother is anxious or distressed, she can be experienced as both familiar and strange by her infant. We assume that from his very early discriminations of familiar persons as well as from familiar ways of being handled the baby comes to learn and anticipate behavioral signs connected with "good mothering." These signs probably include cues from all the various sense modalities. When the mother is anxious her facial configuration is altered by a frown or tight lips, her vocalizations become tense and strident, her handling becomes less graceful and smooth, and it is conceivable that there may be olfactory- sensitive changes in her odors as well. We suggest that there is a shock of "strangeness" in such a situation after the infant has learned to anticipate a pleasurably "good" gestalt of experience. We would also speculate that the *anxious smile*—which we have observed in seven- and eight-month-old infants—may represent in effect a smile of recognition contaminated with the expression of the tension of anxiety. Once infants become mobile—by crawling or walking, or by the early use of mechanical walkers—they are commonly subjected to a multitude of anxiety-

ridden no's. At such times parents become aware of a momentous change in the previously "innocent" relationship, once the socially disapproving modalities come into operation—especially when there are conflict and anxiety in clashing with the child's real or imagined "will." Sullivan and other analysts suggest that "good" and "bad" feeling experiences become organized and grouped in a polarized way, leading to the symbol formations associated with "good-me" and "bad-me" and with "good-mother" and "bad-mother." *Learning through the experiencing and avoidance of anxiety becomes one of the most powerful means through which socialization may then take place.*

One of the mother's—and the father's— major functions in facilitating separation and individuation is to help render the outside unfamiliar world available for exploration. Aside from the practical aspects involved in this function, the parent mediates for her child the new and strange objects, sounds, and people in the environment. We see the origins of what might be called the "magical blessing" when mother, for example, allays the child's fear of receiving and exploring a new toy from a stranger by simply handling the toy and offering it to the child herself. One has the impression that by such mediations the mothering one can detoxify strange, anxiety-laden elements of the environment. She does this, in part, by helping the child cope with the frighteningly strange aspects of his world in ways that allow them to be experienced as engagingly novel or even as partly familiar.[28]

Separation and Individuation[29]

Separation anxiety would seem to be a ubiquitous phenomenon in infancy and remains a lifelong vulnerability at any stage of the life cycle. Yarrow found that by the age of eight months 100 per cent of his sample of infants suffered both mild and severe signs of separation anxiety. He also found that the greater the discrepancy in patterns of maternal care between the first and second caretaker the greater was the postseparation disturbance. Spitz's and Bowlby's pioneering work in this area has already greatly changed our sensitivity to the problems of separation in infancy and childhood to the point of emphasizing the importance of parental presence, if feasible, during a child's hospitalization.

In his studies of attachment, loss, and grief in childhood, Bowlby has revealed what appears to be a frequent sequential pattern of reaction to separation, especially in children over six months and under three years of age. At first the child—especially if he has had a close relation to the mother —reacts with *protest,* crying and searching for the missing mother as if he expects her return. This reaction is followed by a phase of *despair* characterized by intermittent crying, inactivity, and withdrawal, indicating increasing hopelessness and what Bowlby believes to be equivalent to a state of mourning. A third stage of *detachment* follows which is often welcomed as a sign of recovery, although when the mother visits there is a striking lack of

attachment behavior toward her—as if the child had selectively lost interest in the mother. If there is a series of losses of mothering figures, the child will commit himself less and less to each succeeding figure and will develop rather superficial relationships in which people come to be experienced as sources of supplies rather than as special people in their own right. In the extreme of the neglected institutionalized child, one can observe the deterioration of almost every area of functioning, including the development of language, cognition, motoric control, autoerotic activity as well as adequate affective interpersonal relationships.[30] Hence the enormously important public health issue of providing an adequate stable nurturing environment for a child who does not have this environment available in the traditional family setting. *The propagation of defects of early development constitutes one of the widespread human crises of our time* since the relation between such defects and subsequent personal and social pathology is more than merely speculative at this stage in our knowledge.

From the work of Spitz, Bowlby, and more recently Tennes and Lampl, one can postulate that a number of reactions to separation represent prototypical precursors of major human defensive and coping systems throughout life. The infant's reactions to separation include visual avoidance (of the strange substitute caretaker), inhibition of activity, and withdrawal as well as active attempts at mastery, for example, attempting to follow a mother who is disappearing through the door. When active attempts at mastery arc

thwarted, the experience of futility and affects of hopelessness and helplessness ensue. Although we are only referring to research involving overt separation, one can postulate the importance of these reaction patterns to character development in less obvious experiential patterns, involving what might be called "affective separation" or "masked deprivation"—which can occur when a mothering figure is physically present but not adequately stimulating or responsive.[31]

In so-called disadvantaged children, defensive character detachment and precocious pseudoindividuation, with an implicit loss of hope for good relationships, are frequently observable; they partly account for the lack of richness of experience and the failure of adequate cognitive-affective development when "enriched" environments are subsequently made available. Even though human development does not seem to proceed in the rather rigidly defined "critical periods" seen in various other animals, nevertheless, there would seem to be optimal periods during which certain experiences are most productive to the cognitive and social-affective development of the growing child. Deficits in the various stages of infancy described here can be "made up" or compensated for only to a limited degree. This statement is certainly no argument for not attempting later developmental compensations; quite the reverse. Nevertheless, it is clear that our social focus should be on prevention of deficit as well as on attempts to find adequate methods of compensation.[32]

The direction of psychic development in infancy is from symbiotic fusion to individuation with increasing differentiation and structuralization of the ego; this, in turn, permits interpersonal relationships on an increasingly higher level of reciprocity. There are signs of a dawning sense of self in the first year of life as the infant remembers and anticipates experience and comes to discriminate his self, his mother, and others. As maturation and experience—including environmental facilitation—make this possible, the child begins to do for himself and for others what had been done for him: he feeds himself, he manipulates objects and toys, he transports himself, finally in the upright posture. He decides on a course of action even if this means opposing or negating those closest to him. He learns, largely by identification, a gesture and word—"no"—to express semantically his autonomous strivings. It is through decision making, goal setting, and goal mastery that the sense of self is experienced in its most heightened intensity.

With the development of language and locomotion in the second year, we begin to consider the infant as entering a new phase of development, the "toddler" or "autonomous" stage, which is ushered in around 15 months of age. By this time the infant has begun to share his experience with his parents who are—if all is going well—delighted with his humanoid capacities to walk, talk, and begin to communicate his needs and experience.

The very achievement of a sense of self exposes the young child to an

awareness of being observed and evaluated, giving rise to a self-consciousness and a fateful subject-object split in the self that lays the groundwork for shame and doubt. The infant and toddler becomes all too aware that a socially disapproved act will bring a disapproving signal or more subtly, but not less potently, a withdrawal of parental behaviors that have the power to reduce anxiety and induce security. In the child's new stage of awareness of his separateness and vulnerability to loss of self-esteem, it becomes crucial that his induction into the social world proceed with a net balance allowing for zestful enjoyment of activity, mastery, autonomy, and initiative since this is a time when there are increasingly necessary limitations—physical and social—on the child's spontaneous activities.

Notes

[1] See Murdock on the issue of the universality of the family.

[2] For discussions of parenthood that include developmental and intergenerational points of view, see Erikson's eight stages of man, Lidz, and R. Blanck and G. Blanck.

[3] The observations referred to above have been written up in an unpublished manuscript, "Some Early Developments in Parent-Child Interaction." The undertaking was part of a project "Studies in Ego Development" at the Albert Einstein College of Medicine (New York) and was made possible by Grant #HD 01155-01 provided by the National Institute of Child Health and Human Development.

[4] The public health possibilities in helping newly developing families are enormous, although complex. One can imagine parent and child caretaker groups being formed under skilled leadership on a widespread basis with the function of helping parents with problems that have been considered unique, unshareable, and taboo. If we can further develop the professional knowledge and skills in this area of family development, such feelings can emerge step by step from considerations of the practical matters of infant rearing to the more personal issues that beset all parents.

[5] We presume that common myths are part dramatization and part "answer" to certain universal human concerns. Although Laius's action can be linked to his jealous, "immature," authoritarian character, there is yet another side to his mythic action that functions as a cultural expression of the incest taboo. In ontogenetic terms this taboo expresses the

superego imperative that derives, in part, from Laius's own boyhood oedipal strivings.

This type of analysis of the Oedipus myth reveals another motive for Oedipus's death wish, namely, one of *revenge* against the father authority whose son's growth was viewed as an unpardonable threat to the father's exclusive power and possessions. For a further discussion of the "triangular" parental affects in the preoedipal phase, see Fromm's presentation of the issue of authority in the oedipal complex and my own discussion of these matters.

[6] There is more than analogy to the above model in the major transference elements that are brought into the psychotherapeutic situation. The therapist is frequently cast in the role of magic helper by the patient, but he has also been cast into this role—in varying degree—by his own motivations in becoming a therapist. Understanding and working through these mutual needs between therapist and patient constitute a major part of the work of intensive psychoanalytic psychotherapy. If we continue to follow the ensuing issues of family development in infancy, we will see that there is probably not a single dimension —whether it be attachment behavior, separation or stranger anxiety—that fails to be represented in the psychotherapeutic situation, especially if this situation is analyzed in some depth. Hence an understanding of infancy and its salient developmental issues enriches the psychotherapist's work with any age group.

[7] The whole problem of child abuse (including the "battered child syndrome") can only be mentioned here. The rage leading to violence has been connected by the attacking parents to the inability—as they perceive it—to bend the will of the child to obedience. It is not only the

child's *actual* autonomous, defiant, or negativistic behavior that provokes attack but spontaneous behaviors—including crying—that are experienced by the parent as willful and defiant.

[8] We had less opportunity to observe upper- middle-class and upper-class families.

[9] Coleman, Kris, and Provence have described in some detail how parental attitudes and unconscious fantasies are continuously influenced by the child's growth and development. More recent research, for example, Moss, has been even more specific about the fact that different variables such as sex, age, and "state" contribute to the shaping of maternal response.

[10] See R. Levy's exposition of the proposition of the inevitability of guilt provocation in Western cultures, which are constantly aspiring to new standards, thus making it very unclear what—at any given moment—may be "good" or "bad."

[11] Psychoanalysis has systematized the positive and negative oral character traits that presumably derive from the period of infancy. Oral optimism is seen as a consequence of having been adequately gratified in this area. On the other hand, such traits as excessive longing and a compulsive need for acquisition and intake of various kinds have been seen as consequences of either overly or underly gratified oral experience. There are as yet no definitive studies (which would have to be of a direct observational longitudinal nature) to indicate whether there is a definite relationship between oral patterning and such problems as obesity (Bruch), vulnerability to drug addiction, alcoholism, and cigarette smoking.

J. Bruner's work with infants has taught us that four to six week olds can learn to alter their rate of sucking (for example, to suck in longer bursts "to produce" a clearer focus in a projected picture). Moreover, by reversing the conditions the infant can even learn to desist from sucking on his nipple in order to obtain a consequently clearer picture. This kind of work is indicative of the tremendous range of learning that begins to take place in the early weeks of life—even in an area as "drive-oriented" as the oral zone.

[12] This is the kind of individual difference that is most important to psychiatry and psychotherapy because we tend to assume that people have more or less the same degree and quality of need in various modalities, be they oral or contact stimulation. The fact of individual difference by no means diminishes the fundamental importance of the tactile modality to the formation and maintenance of the social bond throughout the life cycle. Witness the emphasis on the use of touch and kinesthetic experience—as attempts to overcome individual alienation—in the encounter group phenomena and the "human potential movement."

[13] D. Stern discovered through a film microanalysis that by the age of three months stable patterns of eye-to-eye contact and eye aversion between mother and infant have already been developed and tend to remain stable for a number of months thereafter. If this work is validated, the implications seem far-reaching for the understanding of the patterning of interpersonal relationships. Such poorly understood, but crucial, phenomena as "empathic" communication (Sullivan)MI and "contagion" of affect (Escalona) may be better understood through the microsignaling visual "ballet" that Stern describes as occurring between mother and child. More speculatively, patterns of visual aversion may

also constitute one of the first anlagen of later classical ego defenses, including denial and possibly repression. Stern's later work appeared after this chapter was written.

[14] Several workers have experimentally demonstrated that one can reinforce the infant's smiling response by responding to his smile with a smile, or tend to extinguish the smile by failing to respond to it. Rheingold and Weisberg similarly demonstrated that an infants vocalizations can be markedly increased by the adult's social responsiveness, in contrast to conditioning by contingent nonsocial responses such as a door chime.

[15] See the classic studies of Spitz, Bowlby, Goldfarb, and the more recent observations of Provence and Lipton, Schaffer and Emerson, and Rheingold.

[16] See Kleeman's excellent description and analysis of this particular form of play. Kleeman does not reduce peekaboo to the mastery of separation anxiety or to tension reduction, but sees it also in its own right as a "form of interaction, play, a social game pleasurable to infant and adult." This kind of playful interpersonal exchange can often take precedence over the activity of nursing.

[17] We suggest the hypothesis that with deprivation of relatively enduring reciprocal social relationships, including playfulness, children and adults will appeal for response by re-creating and communicating the urgent need tensions that had been successful in bringing about a response. Hence, hunger, pain, and later in life various expressions of anxiety, hypochondriac fears, psychosomatic conditions, acting out, and compulsive activity can be understood, at least in part, as *an appeal for responsiveness that has hail no alternatively stable and successful interpersonal pathway.*

[18] Genuine play, whether with words, metaphors, ideas, sounds, or design, is an important basis for the formation of culture. I have elaborated on the theme of social playfulness elsewhere, stressing the quality of lack of immediate purposiveness, which frees the partners to improvise and explore new forms of action, symbolism, and relatedness. The structural development of play in infancy has been studied by Piaget, and more recently a stimulating review of the subject has been offered by Galenson.

[19] A fuller discussion of "masked deprivation" is included in the section of this chapter titled "Separation and Individuation."

[20] The criterion used by these authors to assess the level of achievement of specific social attachment to the mother was that of protest upon separation from her. The assumption here was that the infant had a need for proximity, at least on a visual level; when he suffered a cutoff of such visual contact, he expressed his protest in affecto-motor sounds and movements, including crying.

[21] Reconstructive data derived from psychiatric and psychoanalytic histories indicate that the achievement of object constancy—in the meanings described above—is essential to later mental health. Whether there is a "critical period" for its achievement and whether there is the possibility for compensation are discussed under the topic "Separation and Individuation." Many psychiatric disturbances are associated with the failure to develop stable interpersonal relationships; schizophrenic, schizoid, and sociopathic persons particularly suffer such incapacity. These warps of interpersonal development—as Sullivan refers to them—derive in large part from a failure to achieve a level of object

constancy with one or more significant persons early in life, for a complex variety of reasons. The achievement of object constancy can be unstable and—as we know from work with all age groups—subject to breakdown under stress.

[22] Some other important findings that are relevant to contemporary issues involving new forms of child- rearing include the following: (l). High intensity of attachment correlated with the degree of stimulation by the mother. However, such a conclusion poses a problem of what is cause and what is effect, since certain individual differences in babies may demand higher levels of stimulation. (2). High intensity of attachment also correlated with mothers who respond quickly to demands. Again, the nature and intensity of infant demandingness—probably innate in part—may influence the mother's behavior as well as vice versa. (3). High intensity of attachment was found mostly in families with fewer caretakers.

The "selection" of the infant's principal object of attachment correlated closely with the particular adult's responsiveness to the infant's crying and with the amount of interaction between the significant adult and the child. The authors concluded that the breadth of social attachments is related to the opportunity of interacting with people who will offer relevant stimuli, especially socializing and caretaking functions in the widest sense.

For a discussion of these issues from a cultural anthropological point of view, see Mead Spiro, and Bettelheim, who have studied new forms of multiple caretaking; the latter two authors have examined the kibbutzim in Israel.

[23] S. Brody and S. Axelrad have attempted to describe the development of infantile anxiety in relation to ego formation from a psychoanalytic frame of reference, using direct observations of infants.

[24] More recent work is revealing that perceptual discrimination of the mother—if not the specific social attachment to her—is developed in the early months of life. The fact that caretakers would appear to be interchangeable does not contradict the observations that certain signs of discrimination are appearing concurrently very early in life.

[25] The experimental observations noted here have not been carried out systematically on a sufficiently significant number of infants to allow any solid conclusion about how characteristic these reactions may be.

[26] H. S. Sullivan took pains to point out the understandably magical significance that many people — most particularly schizophrenics—attribute to the power of the eyes, to being looked at, and, we would add, to intense eye-to-eye contact. One of the most comprehensive reviews of the significance of early eye-to-eye contact has been written by Robson. The most thorough exploration of communication by facial signs will probably be achieved through intensive film studies of interpersonal behavior.

[27] Compare Schaffer and Emerson's apparently opposite but differentiating results, presumably due to the use of slightly different criteria for each form of anxiety. Yarrow reserves the term "stranger anxiety" for those infants who manifest active protest or withdrawal.

[28] The psychotherapist has a similar task in fostering the patient's movement from the familiar and

"embedded" (Schachtel) into new areas of experience that had been avoided because of their association with anxious affect. The therapist in this sense is also a mediator who looks with the patient into dark, unknown, dissociated areas and through the therapeutic alliance gradually helps to detoxify both the traumatic and untried areas of living.

[29] M.S. Mahler has made a significant contribution to the process of separation-individuation.

[30] See the classic work of Spitz and Provence and Lipton. The latter authors found that some of the institutionalized children subsequently placed in families, despite some improvement, still revealed serious ego deficiencies such as an incapacity for delay, failure in generalization from learning, overly concrete thinking, and a continuing superficiality in social relationships.

[31] We note in our discussion that hypotheses concerning character development have proceeded largely from research connected with trauma and psychopathology. This is due, in part, to the fact that as yet there are few direct observational longitudinal studies reported in depth to connect patterns of experience with character formation. Moreover, we wish to emphasize that with deprivational and traumatic experience, defensive patterns are evoked in an unbalanced or extreme form, whereas the relatively "normal" range of experience of frustration or periodic separation is—when in proper dosage and at the appropriate stage of development—assumed to contribute to the formation of "healthy" coping capacities and "ego strength." There are, of course, many other sources of character development considered in detail in the psychoanalytic literature, including identification and a whole range of coping mechanisms and ego defenses. See Nagera,

Murphy, and Schecter. Learning—in all its forms—and cognitive styles contribute heavily to ego development. The whole topic of learning and cognition will be considered formally in Chapter 14 of this volume.

[32] For a discussion of attempts at compensatory work with deprived children, see Lichtenberg and Norton's review of the research literature and Deutsch's *The Disadvantaged Child.* For a more extensive review of the effects of maternal deprivation, see Ainsworth's work. Birch has carefully studied the devastating consequences on development of early malnutrition.

Caldwell offers an excellent broadly ranging review of the entire subject of infant care.

Growth and Development During the Toddler Years

John A. Sours

The toddler years commence at about 10 to 14 months, with the beginning of creeping and crawling movements, and extend to the third year, when the child has developed the motor skills, language, cognitive activities, and defenses sufficient for separation-individuation and the autonomy needed for the nursery school experience.[1] This developmental interval is also referred to as the anal-muscular phase; developmentally it lies between the oral phase and the phallic-oedipal phase.

During the anal-muscular phase the child grows from lap babyhood to toddlerhood. Erikson refers to this phase as one of autonomy versus shame and guilt. The erogenous zone has shifted from the mouth to the anus-rectum with the development of anal erotism and a conflicting biological mode—namely, fecal retention and elimination. The phase is characterized by vigorous self-assertion in the service of separation-individuation and

autonomy. The toddler strives for independence as a separate individual with his own identity in the family group. The child acquires a sense of autonomy to combat his sense of doubt and shame. His physical, psychological, and social dependency, however, fosters doubts about his capacity and freedom to assert himself. His urge to prove muscular strength and mobility is ever present. It is hard for him to stay in one activity or space. He wants to explore and accomplish new feats and skills. He is now increasingly capable of controlling his anal and urinal sphincters. His diet has been changed so that his stools are harder, and they are easier to control.

The child in this stage of development experiences intense self and object ambiguity and ambivalence. He wishes to hold on and to let go, not only with his hands, but also with his mouth, eyes, and sphincters. His muscular control is more refined.[2] Movement has developed to the point where he is able to creep, crawl, stand, and walk and also to hold on, clutch, and release. He now has a strong desire to manipulate objects. As the child's locomotion increases, the mother begins to say "no" to him. The "no" is a prohibiting gesture. The mother is afraid that he will hurt himself. The child understands the mother's prohibition through identification and imitates the negative headshaking movements; this is the child's first abstract concept. How is this concept acquired? Spitz has suggested that the sign of negation evolves from the neurophysiological rooting reflex. At six months visual and muscular coordination makes rooting unnecessary for sucking. Sucking is

then changed to withdrawal and refusal when the child is sated. At 15 months the motor behavior has taken on an ideational content. Then the head movement means a refusal. On the other hand, the prototype of the affirmative gesture is different. Head nodding is not derived from rooting. The young infant's neck muscles are not strong enough for extension. From three to six months of age the infant is able to support his head. Visual orientation is then possible. The affirmative head nodding is based on the vertical approach movement of the head to the nipple. The affirmative nodding retains its affirmative function. At two years it takes on an expressive meaning after the negative is acquired.

Early oppositional behavior can be noted in infants. A mother will refer to her baby who is slow to wake up for feeding as stubborn. She sees her child as resistive to being fed. Stranger anxiety at eight months may be confused with shyness and stubbornness. At ten to eleven months displays of independence through rejection of the offered spoon are seen. The child can also spit out food he does not like, an early manifestation of the development of independence, which increases in children up to two years of age. Negativism appears when the child feels a need for protecting this developmental process. Oppositional behavior includes mutism, food refusal, bowel and bladder incontinence, and willfulness. Oppositionalism is not necessarily a displacement from anal erotism; it is intrinsic to the developmental process. Resistance to external influences is the most

characteristic aspect of this behavior, but individual differences are noteworthy. The capacity to resist external influence is the toddler's first flowering of self-determination and autonomy. Oppositional behavior fosters separation, protects against compliance, energizes the child to overcome ego immaturities, and helps him to develop and use his own controls.

The toddler faces separation-individuation with a rate determined in part by neuromuscular and language development. Central nervous system development leads to increased myelination and functioning of the stretch reflex in the gamma afferent loop systems. At 12 months the child is able to pull himself to the standing position, at 14 months to stand alone, and at 15 months to walk awkwardly. His new locomotion gives him a great deal of pleasure but also causes conflicts and struggles with his parents. The maturation of motor function seems independent of learning and experience.

This is not true, however, of language, where maturation and learning work hand in hand. Language hastens the child's integration into the family and allows him to start using secondary process thinking and expression. Under one year he has used principally vowels. From one to two years he switches more to consonants and begins using single words and some grammatical structure. The vowel- consonant reversal after age one occurs because of his introduction to solid foods, the appearance of dentition, the decrease in buccal fat pads, the increase in size of the mouth, and the

attainment of erect posture. Language development is fostered by secondary reward and generalization learning. Identificatory learning is also important in this aspect of development. Girls surpass boys consistently in language until age three, when boys' articulation improves.

Toilet training becomes part of the overall communication between the child and the mother. Reward and punishment are critically involved in this behavioral acquisition. Many children, however, are not trainable until one and a half to two years. And frequently children are not dry at night until well after two years.

The child begins to play at age two, but shows little interest in reciprocal play and affiliation with his peers. Later he is able to play cooperatively in the preschool period from three to five years. In his play he engages in exploratory behavior and learns a safe range of autonomy. He manipulates objects and is able to affect changes in his world. From walking, exploring, and manipulating come some feelings of confidence. His play activity satisfies his intrinsic need to deal with the environment. If a self-initiated response is rewarded, then it is permissible to be curious.

By six months the child tries playing with many playthings in his microsphere or thing-world. In early infancy playthings are soft and cuddly, reproducing the mother's body and providing a transitional object for the

child's security at bedtime. By nine months the child is able to play pat-a-cake and peekaboo with the mother, turning passivity into activity in order to assimilate the anxiety of object loss. Such symbolic play expresses separation from and retrieval of the mother. In the toddler stage movable toys with strings extend this separation play. In addition, the toddler uses socially acceptable substances for symbolic excrement play involving filling, emptying, and messing.

Galenson has extensively reviewed cognitive aspects of nonverbal play. The use of symbols with no fixed meaning and the lack of negation are aspects of primary process thinking as well as presentational symbolism, both apparent in play behavior and its manifestations as nonverbal thinking.

Bowel-Bladder Pleasure and Control and Transformations in Personality Development

With myelination of the neural pathways for micturition and defecation, the toddler is ready to assume control of his sphincters. At the same time the bowels and bladder bccome associated with physiological tension and pleasure. The mother imposes her adult standards on the child to force him to give up pleasurable retention and elimination, as well as play with the feces. She cannot control his sphincters as she controlled his rhythmic nutritive and non-nutritive needs. She now has to negotiate with the child by pleading, begging, and cajoling. This interaction, once thought to be the most important

aspect of toddlerhood before the separation-individuation subphases were recognized, is still central to this phase of development.

The child may retain feces to prolong the pleasurable sensation of evacuation. He may retain to defy the mother, an act that may mark the onset of stubbornness or be a part of his need for mastery. He may retain feces to incur the mother's pleasure. He may let go to defy the mother. Soiling and smearing are hostile acts and are often precursors to anal, urethral, and phallic profanity. The child may urinate and move his bowels to please his parents. The feces may be regarded by the child as valuable possessions, his own creation. The mother may regard the feces as a laudatory product or, on the other hand, as dirt and filthiness. Frequently both attitudes are expressed at one time or another. The child may view defecation as getting rid of something bad or dangerous.

Urination for boys provides an aggressive and libidinal pleasure owing to the powerful stream. This play may evoke envy in little girls. If a child is frustrated too much by toilet training, his frustration may result in chronic anger or in timidity and submission. For boys stimulation of the genitals during defecation often leads to erection, retraction of the testicles, and simultaneous contraction of the sphincter anuses. The stimulation may lead to confusion about whether the fecal mass or the genitals are dropping off during defecation.

In order to understand bowel-bladder pleasure and control and their transformations into personality development, it is necessary to trace the development of anal erotism and body awareness. Anal erotism refers to the drive qualities of the anal phase of development when the erogenous zone has shifted to the anus and rectum. The erotism is experienced during defecation and in connection with anal masturbation and anal retention. Stimulation of the mucus membranes lining the anus and rectal canal leads to erotism. The pleasure is autoerotic. In this way the child negotiates with the mother over sphincter control so that the erotism becomes object related. With the appearance of teeth, the increase in musculature and strength of sphincteric functions, anal and sadistic impulses emerge. As in oral erotism, there are two distinguishable stages to anal erotism. The first is characterized by destructive impulses. The second is reflected in impulses to keep and possess.

Freud first referred to the anal phase in a letter to Fliess in 1897. Freud commented on how money and excrement have long been associated in history. In the 1905 edition of the "Three Essays" Freud described excitation of the anal zone. He indicated that children enjoy anal erotogenic stimulation in holding back stools to the point where the accumulation results in a violent contraction. In addition, he indicated that anal masturbator pleasures are derived from stimulation of the anal zone. In his paper on "Little Hans" he referred to Hans's fantasy of taking big children to the toilet to make them

"widdle" and to "wipe their behinds." Freud felt that the fantasy indicated that Little Hans had been looked after as an infant in much the same way and this had been a source of pleasurable sensations to him. Freud suspected that Little Hans had been a child who enjoyed retaining his feces so that he could enjoy "a voluptuous sensation from their evacuation." In his paper on "Character and Anal Erotism" Freud indicated a connection between anal erotism and character traits of orderliness, parsimony (connected with an interest in the product of defecation), and obstinacy (which is associated with the act of defecation), as well as the child's unwillingness to comply with the mother's wishes. Later he indicated that anal erotic aims are unserviceable culturally and must undergo sublimation. Later in the analysis of the "Rat Man" Freud revealed ways in which anal erotism appeared in the man's illness. For the "Rat Man" the rat had many meanings such as money, worms that bury in the anus, and dirty animals feeding upon excrement. In "Disposition to Obsessional Neurosis" Freud indicated that there is a pregenital sexual organization, thus using for the first time the term "pregenital." At this point of development he thought that the component instincts have already come together for the choice of an object and that the primacy of the genital zones has not yet been established. He believed that the component instincts that dominated the pregenital organization of sexual life are the anal erotic and sadistic ones. He also indicated the mechanism of reaction formations against anal erotic and sadistic impulses and the

possibility of regression in instinctual life to the pregenital sadistic and anal erotic stages.

Freud characterized the sexual aim of anal erotism as two in number, active and passive. Activities are supplied by instinctual mastery. The passive trend "is fed by anal erotism whose erotogenic zone corresponds to the old undifferentiated cloaca." In "Three Essays" Freud stated that "the activity is put into operation by the instinct for mastery through the agency of the somatic musculature; the organ which, more than any other, represents the passive sexual aim is the erotogenic mucus membrane of the anus. Both of these currents have objects which however are not identical."

In 1917 in "The Transformation of Instincts with Special Reference to Anal Erotism" Freud remarked on the complex unconscious relationship between the ideas of feces, child, and penis. He later elaborated on this in his study of the "Wolf Man" who preferred copulation from behind and was attracted to the female buttocks, all part of his anal erotic disposition. And in "Three Essays" Freud further elaborated on the unconscious meaning of feces, suggesting that they are at first for a child a "gift" and later acquire the meaning of "baby," one of the sexual theories of children. In his study of the "Wolf Man" Freud also concluded that the fecal mass stimulates the erotogenic mucus membranes of the male and is the active organ just as the penis stimulates the vaginal mucus membrane. In this sense the fecal mass

acts as though it were a forerunner during the cloacal period. Freud felt that giving up feces was a prototype of castration, the first time a child is made to part with a piece of his body in order to gain the love of an object. Feces, baby, penis thus all form a unity, "the little ones" that can become separate from one's body.

In another paper Freud remarked that the child must dccide between a narcissistic and an object-loving attitude. As he makes the choice of autoerotic satisfaction and becomes defiant, his attitude comes from his narcissistic clinging to anal erotism. He remarked that a large part of anal erotism is carried over to the eathexis of the penis. He further remarked that fantasies of patients were filled with the equation of feccs-money-gift-baby-penis. Interest in the vagina occurs later and springs from anal erotic sources. He quoted Andreas-Salome, who referred to the vagina as "taken on lease" from the rectum; this is most commonly seen in the fantasies of homosexuals, where the vagina is represented by the rectal canal.

Thus Freud viewed the anal phase as the second phase of libidinal development in which the discharge of dammed up instinctual energy is connected with the act of defecation and the accompanying pleasurable sensations. The child's interest at first lies in retention and expulsion of feces, which he regards as a valuable creation, a prized personal possession, that unfortunately he must eventually relinquish. Finally the child repudiates his

anal wishes and sublimates the energy into activities such as playing in the sand, staying clean, and painting. If the child is not permitted to give up his anal investments slowly and is forced into a traumatic situation, he is apt to use the mechanisms of repression and reaction formation in an attempt to rid himself immediately of such interests. Repressed unconscious anal wishes may continue to play a large part in his life and produce various warped defense mechanisms.

The Creation of the Representational World

The child creates his representational world out of images of the external world that he comes to experience as the "external" world. The representational world also contains the child's own body sensations as part of his body schema, along with representations of instinctual drives as need and affect representations. Piaget has studied the maturational process by which images are formed into lasting representations during toddlerhood (about 16 months). At this stage object constancy is perceptual, followed at about 36 months by libidinal object constancy. From body representations arise self-representations, which are enriched by activities, experiences, identifications, and, with the resolution of the Oedipus complex, introjection of parental authority.

From the development of sensorimotor and representational

intelligence the toddler's representational world arises. Piaget has described this process over a period of some years.

The neonatal cycles of tension—quiescence, sleep, wakefulness—continue through the first year. A fatigued and satisfied infant goes to sleep until hungry and restless. If not immediately fed, he then begins sucking his finger, which gives him experience in eye and mouth activity, the basis of primary circular reactions. This activity leads to tension reduction by mental images that are satisfying for a while until hunger increases, and the infant cries and becomes more restless. The mother then responds with milk. The infant then lies in an alert, active state, playing and exploring to the point that he again becomes fatigued and falls asleep. Thus the sleep-waking cycle is completed. Sensorimotor intelligence is dependent for its development on gratification of instinctual needs.

Whenever the infant's oral needs are satisfied, the baby uses sensorimotor schemata for explorations and short excursions by which he acquires increasing knowledge of his environment. He explores his world until fatigue sets in and he is forced to go to sleep.

During the first two years of life the child goes through six stages of cognitive development. The basic biological processes whereby he acquires knowledge are assimilation and accommodation. By assimilation Piaget

means that the organism takes in aliments from the world about him. He makes constant perceptual and motor adjustments to the world on several levels. At the biological level there are physiochemical incorporations into the organic structure of the body. At a primitive psychological level the organism incorporates sensory and motor components of behavior into endogenous reflex schemata that are then activated in later psychological development. The mind incorporates ideas about the external world and products of mental activity into already existing schemata of sensorimotor activity. By accommodation Piaget means a process whereby what is assimilated is so changed as to bring about an adjustment within the environment. Accommodation modifies the experience of new stimuli or conditions. Intelligence is a capacity to distinguish objects from the self in respect to space, time, and form. It is a capacity to manipulate intrapsychically symbols and schemata to solve problems of the environment. The child's cognitive development is facilitated when his instinctual needs are satisfied and he is provided with a sense of safety by the mother.

The first stage in the development of intelligence (birth to four weeks) is made up of reflexes needed for survival, such as sucking, rooting, and grasping. These reflexes are the building blocks to intelligence. At this stage of development the baby is able to differentiate the nipple from the blanket. He can recognize satisfying or unsatisfying objects. Successful repetition of the reflexes results in an assimilation in the neural apparatus. The assimilated

pattern of behavior is called a schema, which may be a mental experience and at a later stage an image. It is an adjustment to the environment.

At the second stage the primary circular stage (one to four months) the infant practices rhythmic mouthing and hand movements. He watches his mother and visually pursues her. The sensory stimuli in his environment provide the aliments for activity. The human face is a visual schema. The human voice is an auditory schema. At four months sucking becomes adjusted to a new type of schemata. The assimilation of grasping and visual pursuit leads to new accommodations. The child is now able to grasp what he sees. He now is capable of intersensory coordination, but he is still not able to identify things in space as having identity. For instance, if a toy is hidden under a cover, the toy is totally lost to him. The image is no longer a stimulus when the object is gone.

The third stage is the secondary circular reaction (four to eight months). It is the first time the infant performs an intentional act. The baby acts upon things and uses relationships as a means toward an end. For instance, he will grasp a suspended rattle, strike it, or swing it. If he is supine he will swing at the rattle rather than grasp it. He will practice with pleasure. He may make the rattle swing by shaking the crib. Thus the schemata are reciprocally assimilated. In following the mother, the baby will use these gestures to perpetuate a variety of spectacles. He may induce another person to make the

rattle move. Still objects have no independence outside of the movement of the baby in respect to them. For example, if an adult hides a ball under a cover, the baby will look for it as an extension of his own visual environment, or he will look into the adult's hand. There is now some kind of permanence of images for him at this stage. Space has become a function of the images of prehension and motor activity; which exist in a trajectory of visual and motor activity. This marks the beginning of interest in causal relations. Imitation begins as a means of inducing a person in the environment to repeat interesting acts.

The fourth stage, coordination of sensory schemata and their application to new situations (eight to twelve months), is a stage in which the infant assigns to external objects a consistency independent of himself, but without permanence. He pursues ends not immediately attainable. For example, if an object is hidden, he will remove the object with one motion and then take hold of it with another. He has the capacity to keep in mind his goal. He uses instruments as intermediary means to an end. For instance, he will push the adult's hand away. Signs and symbols indicate specific events. At this stage the infant will turn toward the sound of footsteps. He will explore objects as though trying to understand them. He will grasp relations between size and distance. He is now well aware of three dimensionality. In this stage eighth-month anxiety appears with the recognition of the mother's face. He can now only tolerate short separations.

At the next stage, tertiary circular reactions (12 to 18 months), the baby discovers new means to active experimentation by adapting himself to unfamiliar situations not only by using schemata acquired earlier but also by seeking and utilizing new means to do it. He no longer is satisfied with producing familiar results. If he has a new toy, he will feel it, pick it up, drop it. His interest is taken up with what is new and different about the toy. He may also, for instance, take a ball and roll it and delight with the new activity he has given the object. He will search for novelty and be overjoyed if he finds an entity that can be made to do different things. He may use a stick or string to bring things nearer. Spatial and causal relations are extended. For instance, if a ball is hidden at point A, he will find it. If the ball is then hidden successively under B, C, and D, he will go immediately to D. He is able to take into account visual displacement. Objects have an identity and a relationship to continued perceptual cues that reach the baby's mind.

The child is capable of discovering and utilizing complex relations among objects. This is possible through extensive experimental study of distance as well as space. He studies movements of objects from place to place. The exploration of equilibrium, rotation, reversals, positions, and content is possible, yet knowledge of the relationships does not transcend perception.

In the sixth stage of development (beginning at 18 months) the

invention of new means through mental combinations marks the start of true intelligent behavior. The child is able to conceive of objects as entities with dimension, qualities, spatial, temporal, and causal relations, even when the objects are no longer perceived. Thus the child has attained conceptual object constancy. He forms mental representations that include the object not only as it is actually perceived but also as it might appear under other circumstances. External objects are identical to the self, separate from the self and his actions, regardless of how displaced or hidden. The child will search for hidden objects or displacements not visible to him. He is able to imagine displacement in space and to internalize cause-and-effect relationships. The child's body can be subjectively experienced as an independent object, differentiated from inanimate objects and from persons. He now has the capacity for mental representations of the self.

At the end of the 24 months the child enters a new phase of intelligence. He has left the sensorimotor stage of intelligence and is now in the period of preparation for the organization of concrete operations. Now the child is capable of crude symbolizations. Piaget has divided this phase of development into two parts. In the preoperational representation phase, from two to four years, there is the beginning of representational thought. Then from four to five and a half simple reproductions or intuitions occur, followed from five and a half to seven by articulated representations or intuitions. At age seven the child enters the stage of concrete operations. He is now capable

of conceptual organization that takes on stability and coherence by series of groupings. After age 11 to about 15 the child is in the period of formal operations. New structures, visuomorphic to groups and lattices of logical algebra are now possible.

Separation-Individuation during the Infant-Toddler Years

Through her early studies of young psychotic children, Mahler has identified and described the process of separation-individuation during the first three years of life. Many of her concepts relate to or interdigitate with those of Piaget and Sandler. She has helped develop the view of the life cycle as involving progressive stages in distancing from and internalizing the symbiotic mother and negotiating the eternal longing for the actual or fantasized "ideal state of self"—a symbiotic fusion with the "all-good" symbiotic mother, who at one point in infancy is part of the self, as the core to the blissful state of well-being.

During the neonatal period the infant attempts to achieve homeostasis, at first through the help of the mother and later through the development of increasingly protective neuro- physiological mechanisms. The infant begins to differentiate between pleasure and pain through expulsive activity and maternal gratification.

By the second month of infancy he begins to have an awareness of need-

satisfying objects. Mother and infant are a dual unity with a common boundary. At this point there is no difference between the "I" and "not-I." The inside and outside are experienced together. At this point the infant has formed a maternal symbiosis that strengthens the inborn instinctual stimulus barrier and protects the child from premature phase-specific strain. The symbiosis is an hallucinatory somatopsychic omnipotent fusion with the representation of mother and the sense of common boundaries. It is necessary that displacement of libido take place from the inside to the outside of the body.

During the normal autistic phase there is an absolute primary narcissism. The infant is unable to differentiate between "self" and "not- self." By the third month, however, there is increasing awareness of need satisfaction coming from part objects. Still the infant views the outside as continuous with an omnipotent, symbiotic dual unity. Gradually there is demarcation of the representation of the body ego from the symbiotic matrix. The body ego becomes increasingly differentiated. There is a shift of proprioceptive and enteroceptive cathexis to sensoriperceptive cathexes of the outside world, which is essential to body ego formation. In addition, there is rejection by projection of destructive aggressive energy beyond the body's self boundaries. The infant begins to develop an inner sensation for the core of the self. Feelings of the self form the beginnings of a sense of identity. The sensoriperceptive organ further demarcates the self. Object relations start to

develop as the infant differentiates from the mother-infant dual unity and enters a normal phase of human symbiosis. There then is a transition from lap babyhood to toddlerhood; this progresses through steps of separation-individuation only made possible, on the one hand, by autonomous ego development and, on the other hand, by a host of identificatory mechanisms. The process of growing away from the baby- mother symbiosis involves a mourning process, which, as part of every step toward independent functioning, is associated with the threat of object loss. This is especially prominent in the separation-individuation process from the fourth to fifth month to the thirtieth to thirty- sixth month. The separation-individuation phase has been divided by Mahler into four subphases: differentiation, practicing, rapprochement, and "on the way to libidinal object constancy."

The first phase, differentiation, takes place from four to five months of age at the peak of symbiosis. In the symbiotic months the infant comes to identify the mother as the specific object toward whom he forms a specific bond. The symbiotic unit is created through entero-proprioceptive and contact-perceptual information. Sensoriperception attention-cathexis expands his perception beyond the symbiotic orbit and fosters a perceptual conscious system and a permanently alert sensorium during periods of wakefulness. From six to seven months the child is fascinated with the mother's face and body, which he explores with his available sensory modalities. In addition, he plays peekaboo games. He is now able to recognize

his mother and check out unfamiliar objects against the already familiar; Brody calls this activity "customs inspection." He attempts for the first time to break away from his passive lap babyhood. He does this in miniscule ways by pushing back from his mother's hold, sliding down her lap, and sitting at her feet, all providing him with increasing distance from the mother and new views of the maternal object. As he sees new objects distinctly different from his mother, he experiences "stranger reactions." He is curious about and full of awe at every new strange thing he sees. If he is trustful of his mother, anxiety is manageable.

The second phase, practicing, overlaps the phase of differentiation to some degree. The second phase occurs from seven to ten months and lasts up to fifteen to sixteen months of age. Activity in this period justifies dividing this phase into two parts: (1) the early phase, which overlaps differentiation and is marked by the infant's early ability to push away physically from the mother through crawling, righting himself, and climbing, yet at the same time holding on; and (2) the practicing phase proper, which is characterized by free, upright, bipedal locomotion. The child's increasing awareness of separateness is involved in rapid body differentiation from the mother, the establishment of a specific bond with her, and the growth and functioning of the autonomous ego apparatus in close proximity to the mother.

Because of his new relationship with the mother he can now look

beyond her at other human and inanimate objects. He can play with toys of all sorts and explore them with his eyes, nose, hands, and mouth. One or more of these objects are apt to become transitional objects. Part-objects of the mother are used to assuage anxiety during her absence at night. During this phase of development the infant must move and explore. As he does so he makes brief sorties away from the mother, returning periodically to "home base" in order to refuel through physical contact. In this early practicing subphase there are brief periods of separation anxiety. The infant tries not to lose sight of his mother. Much depends on the mother's comfort in seeing the child moving away from her. Walking has for the mother, as for the child, an enormous symbolic meaning. If she is able to believe that the child is capable of moving progressively away from her, she contributes to his feeling of safety, and perhaps as Sandler has indicated, he gives up some of his magical omnipotence for autonomy and developing self-esteem.

In the practicing subphase proper, once the child attains upright locomotion, he has, as Greenacre has said, a "love affair with the world." Libidinal cathexis goes into the service of the growing autonomous ego and its functions. The child appears to be ecstatic with his new faculties and the wonders of his new world. He seems to regard himself as indestructible by injury. He acts as if he could not care less about his mother's presence. His relationship with his new faculties and world is also a defensive maneuver to avoid absorption into the mother's protective sphere. The toddler has now

gone from a passive peekaboo game to an active game that aims at avoiding reengulfment by the mother. By fleeing from her he is able to retain her actively, as she eventually catches him and reminds him of her potential comfort. He plays these games and activities in various moods. Although he gives a semblance of indifference to the mother's presence, he nevertheless returns periodically, seeking a sense of physical proximity. The toddler's moods become, as Mahler has phrased it, "low-key" only when he is aware that the mother is absent. His motility diminishes as docs his interest in his surroundings, and he appears to be preoccupied with inwardly concentrated attention, which has been called "imagining." The low-keyness has been compared to a miniature anaclitic depression. If the child is separated from the mother and a different person returns to comfort him, he is apt to burst into tears. When he is reunited with the mother, his low-keyness diminishes. Mahler believes that such behavior results from the child's effort to hold onto a state of mind that Joffe and Sandler have termed the "ideal state of self."

The third subphase of separation-individuation takes place from 16 to 25 months and commences with the mastery of upright locomotion and a diminishing excitement in that ego function. The toddler is now increasingly aware of physical separation. He is now not quite so resistive to frustration; neither is he as seemingly indifferent to the mother's presence. Increasing separation anxiety and awareness of object loss is apparent. His behavior becomes much more active with the mother. He now wants his mother to

share with him all his new skills and experiences. Mahler has referred to this subphase of separation-individuation as the period of rapprochement. The earlier refueling type of contact is now replaced by a quest for constant interaction of the toddler with the mother, most markedly evident in both vocal and nonvocal communication, as well as symbolic play. The toddler now begins to experience the impediments to his anticipated conquest of the world. With the marked increase in autonomous ego functions, there is an increasingly clear differentiation between intrapsychic representation of the object and self-representation. At this point the ego has created a representational world. As he reaches toward a greater height of mastery, it becomes apparent to the toddler that the world is not quite his oyster; he realizes that he must learn to cope with increasing independence even though he is still a relatively small, helpless individual unable to command the world by voice, gesture, and feeling since he has relinquished much of his omnipotence. One finds the child now actively wooing his mother; this is often perplexing to her because he should now be more independent and self-assertive. Frequently mothers during this phase find the child's demandingness unbearable and inexplicable. Other mothers find it difficult, even if the child does return to woo her, to view the child as increasingly independent and separate. In the third subphase individuation proceeds very rapidly just as the child is becoming increasingly aware of his separateness and uses a number of ploys to avoid separation from the mother. He finds that

he must use verbal communication more and more with his mother. Gestural communication and preverbal empathy between mother and child no longer provide the same sense of satisfaction and well-being that they used to. The junior toddler realizes and must accept that his parents are separate individuals with their own individualistic tendencies and interests. He is forced to give up the delusion of his own omnipotence and grandeur. This Mahler has termed the rapprochement crisis, the crossroad where three basic anxieties of early childhood come together: namely, the fear of object loss, the fear of loss of love, and signs of castration anxiety. It is the crossroad between fusion and isolation, part of the lifelong struggle with separation-individuation.

The fourth subphase of separation-individuation is that of increasing attainment of object constancy in the Hartmann sense. The child is "on the way to object constancy." This subphase occurs from 25 to 36 months. At the beginning the child is gradually able to accept once again separation from the mother as he did during the practicing subphase. The verbal communication that had begun during the third subphase develops very rapidly during the fourth phase and replaces to some degree gestural language, affective motility and primary process language. In this regard the mother must often play along with the toddler, providing him with secondary process language and ways of viewing the world. In addition, the toddler in this subphase shows a more constructive and purposeful type of play, often associated with fantasy,

role playing, and make-believe. The child is increasingly interested in adults other than the mother. His sense of time develops along with a capacity to tolerate delay of gratification. He is better able now to endure separation at a time when individuation is also progressing. Oppositional behavior is more prominent than during the rapprochement phase. Now he actively resists the demands of adults and at times is quite negativistic in his behavior.

As the child is "on his way to object constancy," he obtains a unified representation of the parental object, which then becomes in- trapsychically available to him as a love object. Now separation and individuation are more closely connected to developmental processes. Yet if development is disturbed, they can proceed divergently as a consequence of the lag in one or the other. If a rapprochement crisis occurs, it may result in unresolved interpsychic conflict, which is then established as a fixation point interfering with later oedipal development.

Oral, anal, and early genital forces and conflicts are found at the time of the rapprochement crisis. Symbiotic omnipotence must be renounced in the face of increasing awareness of body and its sensations and pressures at zonal points. Awareness of bowel and urinary sensations during the toilet training process can heighten the child's reaction to the discovery of anatomical sex differences, causing him prematurely to experience castration anxiety.

The father's role in separation-individuation is not as clearly defined, partly because of his lesser importance during the early infancy months. The baby's relationship with the father begins during the symbiotic phase, as manifested in the infant's smiling response to the father. At this time the father becomes somewhat familiar to the infant and is no longer just an object toward whom he may experience stranger anxiety. From the very beginning of infancy the infant is more reactive to the mother and even to siblings than to the father. In the differentiation subphase attachment to the father occurs, but it becomes pronounced only at the beginning of the practicing subphase, at which time the father is truly the second parent. The father is now the more interesting object, in space away from the mother and readily available for exploration. The infant's elevated mood seen during this period is most conspicuous with the father, with whom exuberant play takes place.

It has been observed that girls attach themselves to the father earlier than boys and are more cautious with strange men and with all unfamiliar people. Boys are able to approach male objects earlier, a fact probably related to their greater interest in distance, space, and inanimate objects. Even at the age of two years girls tend to be passive in seeking affection from the father and his substitutes. Boys, on the other hand, are more distant and show a dichotomy between the symbiotic and the nonmaternal world.

Toward the end of the practicing subphase toddlers seek out the

attention of more than one adult. Children of this age are quite competitive, manifesting considerable envy and aggression toward one another. Competition toward the father is not evidenced at this point, but the child's relationship to the mother shows increasing ambivalence during the rapproachement crisis. After the beginning of the rapprochement crisis the paternal object appears in the fantasy world of the toddler as a more powerful parent. This image of the father may be essential for the attenuation of the child's ambivalence to the mother during the rapprochement position. The child at this stage has three mental representations, those of the self and parental objects, which provide the necessary triadic elements for the Oedipus complex.

Roiphe and Galenson have found that in the separation-individuation phase, particularly between 15 and 24 months, there is increasing genital manipulation, masturbatory activity, and curiosity about and reactions to anatomical sex differences. They suspect that there is at this time an increase in endogenous genital sensations, associated with bowel and bladder activity, that is probably independent of toilet training. They suggest that this part of separation-individuation be considered an early genital phase, necessary for consolidation of self and object representations and the establishment of a primary schematization of the body and genital outline. They have found that castration anxiety is apparent after awareness of anatomical differences for some children who have not formed stable body schema. Castration anxiety is

most apparent in those children who have suffered physical illnesses, surgery, or birth defects or have lost a parent. Their observations come from nursery school experiences, but analytic child and adult data also indicate much the same thing. During the rapprochement phase the vulnerability of this subphase is heightened if the child experiences excessive castration anxiety. The anxiety leads to a regressive breakdown of toilet training, with massive enuresis and negativism. The child's increasing ambivalence results in splitting of the good and bad mother images and turning of aggression against the self, with depressive mood and collapse of self-esteem. Castration anxiety weakens ego functions and brings about inhibition of curiosity and play.

Studies of the early genital phase indicate that children are well aware of genital parts and are readily upset by becoming aware of genital differences. It is not unusual for toddlers, if given the opportunity, to examine each other's genitals. A little girl may reach out to touch a boy's penis in order to sec whether the penis is really there or to give vent to an incompletely inhibited aggressive impulse to take the penis.

Toilet training has traditionally been viewed as an activity imposed upon the child by the parents, with the expressed aim of giving the child autonomy, but at the same time making the child struggle for independence. The toddler's sexual curiosity, interest, and activities are also typical of this period and have strong influence on the entire toilet training process.

Castration reactions at this phase can disrupt toilet training and, if part of the rapprochement crisis, deflate the child's selfesteem at a time when he is already bereft with the loss of his omnipotence and the uncertainty about the presence and availability of his mother. With dissolution of the toilet training routine, the child is put into a further crisis with the mother and is more apt to develop a hostile, dependent, paralyzing relationship with the mother.

With the attainment of bowel-bladder control and libidinal object constancy, the child enters firmly into the triadic world of his family. Growth and development during the phallic-oedipal phase is discussed in Chapter 14.

Chapter 14

Growth and Development in Childhood

John A. Sours

Psychosexual development has a central place in all phases of child development and personality formation. Its influences and transformations affect all aspects of the developmental process. From the standpoint of physical sexuality, however, there are no appreciable changes before puberty between the sexes. Sex hormone production for both boys and girls involves small amounts of estrogens and androgens. Androgen production is increased in both sexes, more marked in boys, at about age nine to ten, with subsequent sharp rises in adolescence. The excretion of estrogens gradually rises in both sexes from about the age of seven.

Psychosexual development, on the other hand, entails many more preadolescent changes than those of physical development. These developments are apparent in a child's increased sexual masturbatory activity and explorative interests, his awareness of genital differences, his preoccupation with theories about the creation of babies, his attraction to the

contrasexual parent, and his castration anxiety. In the phallic-oedipal phase of psychosexual development numerous changes occur independently of hormonal change. The phallic-oedipal phase of development has also been called the nursery school years, the preschool years, and the stage of initiative versus guilt. Although this phase of development occurs between the ages of three and six, there are variations in its chronology from child to child. In some respects many developmental issues during this phase overlap the age span of three to six years. This fluidity between psychosexual stages is clearly seen at both ends of the phallic-oedipal period. Mahler, Roiphe, and Galenson suggest that sexual arousal can occur before the second birthday; for some children, who observe differences between the sexes, distinct castration reaction can also occur this early. Although many character traits are discernible by the age of five years and have some permanence, character structure is subject to future modification and emendation during latency and adolescent years before consolidation at the end of late adolescence occurs.

The phallic-oedipal phase has a number of component parts. The phenomena of infantile sexuality include discovery of sex differences, erotic genital exploration, sexual curiosity, sexual play, attachment to the contrasexual parent with expectation of loss of love, injury, and retaliation from the isosexual parent, and castration anxiety. Castration anxiety, however, is most nuclear of the developmental conglomeration and is a pivotal force in the creation and dissolution of the oedipal situation. During

the anal-muscular phase of development, especially the subphases of differentiation and practicing, the toddler attempts to increase his experience and capacity and reaches libidinal object constancy at about 36 months. With his entry into the phallic years he experiences another burst of energy, curiosity, and initiative. Erikson has referred to the phallic-intrusive mode as the descriptive and dynamic hallmark of this phase of development. "Being on the make," "making," and pleasure in the "conquest" are colloquialisms for this phase of development. This intrusive quality is more prominent in boys, but, nevertheless, it has its parallel in girls as far as "catching," reaching out, "being on the make," and being attractive and endearing.

At this point of development the phallic child is capable of conceptualizing his place in his family and his relationship to people in his immediate community. According to Mahler, at the end of the fourth subphase of separation-individuation (36 months) the child has attained object constancy in the Hartmann sense and has established mental representations of parents and self. He now has a social role in his group that allows him, among other things, to delineate more clearly his self and gender representation. After the age of three or four years he is repeatedly exposed to environmental reminders that he is no longer a small child. On the other hand, his intrusiveness quickly brings him by way of frustrations to the realization that he is hardly an adult. Consequently he repetitively experiences defeat and humiliation in his competitions and in his everyday

interactions with his family, nursery school teachers, and his peer group. To some extent his aspirations inevitably must be dampened. As he goes through the phallic-oedipal years, he fumbles his way through his frustrations and failures and tries to remain hopeful.

As his awareness of himself within the matrix of his family increases, he queries more and more his exact relationship to his parents. He starts wondering about pregnancy and birth and how he came to be born. Even if he has been instructed in sexual facts by his parents or has witnessed sexual intercourse, he still must, by virtue of his level of capacity and emotional life, strive to create his own theories of intercourse, pregnancy, and delivery. He wonders in many ways about pregnancy, curious about the possibility of his mother having more children; he raises questions about his own ability to have a baby, even with his father. He is now more inclined to ask his mother, not too sheepishly, whether he can marry her. Often he sees no incongruity in his intent, but whatever he fantasies and initiates in reality only reinforces his sense of inferiority, anxiety, and guilt. His wishes pale before reality. He is smaller and less strong than adults. He cannot run as fast and, in fact, is quite apt to trip and fall. His ability to throw a ball is most likely better than his sister's, but he cannot throw as well as his father. Now he tries to drive his father's car, but the best he can do is to sit on his father's lap, only to have the wheel taken from him as soon as the father notices an oncoming automobile. He wants to help his father cut the grass, shovel snow, and rake leaves. These

tasks challenge his strength, and he becomes fatigued more quickly than his father. If his father has mechanized yard equipment, he is told to stay away lest his foot or hand be cut off. His father takes him out to show him how to play tennis or golf. It is bad enough that he cannot play these sports as well as his father. He is further humiliated in the locker room when he notices the smallness of his genitals. He wonders how he will ever be able to fill his father's role. All his experiences as a failure reinforce his feelings of smallness and his awareness of genital smallness. The phallic-oedipal struggle meets with defeat—much like his experience in toilet training—when he attempts to assert his power and autonomy. His is a hopeless fantasized situation that leads to guilt and resignation. The joys of his power fantasies turn to the horrors of his monster dreams.

The girl during phallic-oedipal years experiences no happier an existence. She, too, is frustrated in many ways and fails every day. She tries to help her mother with household chores, but she is always told that she cannot do sufficiently well. Often her job is said to be taking care of her little brother or sister, whom she deeply resents and is tempted to hurt surreptitiously. When she looks at her younger sibling, she cannot help but feel that she would be a better mother than her own mother. Often she makes invidious comparisons with her mother, noticing how inept the mother is in doing household chores and how lacking the mother is in her tastes and manners. The mother's cooking is hardly gourmet enough for the girl's father. The

mother is getting older and older, so much so that no longer will she even reveal her age to her daughter. The girl at this time can hardly imagine why her father continues to show the mother so much attention and, even at times, love. Before the father comes home the girl quickly dresses up for him. She rushes to her closet to pull out a new dress that only that day she was able to buy over the objections of her mother. As the father comes home, she rushes to show him her new dress. His response is enthusiastic. He may even be adoring of her. Too quickly does the girl see that the father's attention is directed, instead, to his wife. He tells his wife about what happened during the day, his various business or professional successes and disappointments. The mother then regales the father with the events of her own day, with the result that the girl is ignored, left only with the prospect of having to help the mother set the table or feed her little brother. Thus the girl at this time feels increasingly annoyed with the mother. She views the mother as inadequate and lacking, wonders whether she too may be deficient in the same manner, and strives all the harder to make an impact upon her father. Nevertheless, regardless of her efforts, her charms, and her beauty, the father's attention to her is interrupted by his involvement with his wife and his preoccupation with his work and with social interests, which take both him and the girl's mother out of the house.

It is readily apparent, both in clinical work and direct observation of children, that in order to reach the phallic phase of psychosexual

development and to proceed on to resolution of the oedipal complex, a remarkable degree of maturation'' and learning is necessary. In addition, the child must go through many socializing experiences within both the family and the peer group.

In the age span from three to five years physical growth accelerates. The average boy grows about five inches and gains almost ten pounds. The average girl is slightly shorter and lighter. Physical growth is very rapid during the preschool years; in fact, by the fifth year 75 per cent of the weight gain is due to muscular development. However, the central nervous system develops most rapidly during the phallic period. When the child reaches age five, 90 per cent of the nervous system has attained an adult level of maturation. Myelination is now almost completed in the higher brain centers, particularly the cortical and subcortical areas. Even though the genital organs are physically immature at this time, the neural organization involved in erotic excitation and orgasm is developed. Its threshold for stimulation, however, is comparatively high and remains so until androgens are secreted in puberty. Heightened androgen production lowers the threshold for erotic stimuli.

Improvement in psychomotor coordination and physical dexterity are encouraging to the phallic child. By the age of four years the child is capable of smoother movements, faster running, and stronger broad jumps. His

movements are finer, more synchronized, and less total. Nevertheless, the child still shows awkward movement in various activities. Overhand throwing is still rough and unpredictable in its accuracy. By the time the child is five his sense of balance is markedly increased, but, nevertheless, he is still not capable of hopping, skipping, and jumping smoothly. Fine digital movements, however, are quite good and are appreciated by the child as soon as he enters kindergarten and first grade. Now he is able to pick up pellets quite easily, draw straight lines, copy squares and triangles. As a result, he has many adult motor patterns that allow him to use tools and more complicated toys with some dexterity. He is a better competitor in sports, at least able now to stand at bat and make a valorous try at hitting a ball. With all these new motor skills he tries to play out various roles. He may be the engineer or the truckdriver or the athlete or some other model figure. He seems to enjoy the status of power and control in the child's world.

Language development has gone beyond basic phonemes to simple sounds or morphemes, which develop by the time the child is three. Morphological rules, necessary for the construction of words, and syntactical rules are increasingly grasped by the child when he reaches the age of five. Consequently, the five-year-old child can organize sentences with a good choice of vocabulary. Through the use of words the child is now not as dependent upon fantasy and ludic play. He is now better able to establish connections between thoughts and words. And with his improved

communicative capacity he is able to make greater strides toward awareness of meaning in object relations. He can use language to describe, classify, and comprehend better the phenomena that he encounters every day in his world.

By the time he is three he uses words in an undifferentiated and syncretic way. Words stand for objects and events as well as actions and fantasies. For a three-year-old a dog is a class of all animals with four feet. A child syncretically thinks of words such as "eat" as meaning food and being fed, as well as the process of eating. By the age of five, however, words are differentiated into meanings to apply to specific objects and events. Classification of objects and things in common is now possible.

In his object relations the child remains egocentric up to the age of four to five. He cannot put himself empathically in the place of others. As he passes through the phallic-oedipal period, his object relations become more sociocentric. His speech is more socially oriented. Fantastic and symbolic play is less needed as a child moves during the latency years into sociocentric communications and relationships with his peer group. The child now has less need for imaginary companions. There is less need for dramatization of different roles.

Perceptual capacities increase as the child enters the phallic-oedipal years. A preschool child can better differentiate stimuli in his environment.

Stimuli become much more distinct when specific language labels can be applied to them. By the time the child is age five, he can label the component parts of stimuli. He is now able to attend to both the whole and the parts. A five-year-old, however, has difficulty in detecting differences between shapes and mirror images. Only with increasing age can the child regard spatial organization of objects as a relevant dimension. This is due in large part to his learning the labels "right" and "left" as well as "up" and "down."

It is very difficult to separate perception and language from cognition in any study of intellectual development. Intellectual ability is dependent upon the acquisition of language, increasing memory capacity, the differentiation of perceptual experience, and the learning of rules of mathematics and logic and their application. Between two and four years, according to Piaget, a child can form a representational world. During the preconceptual phase of intelligence the child develops a symbolic representation of the world, lie requires labels for the things that lie now perceives. From the age of four to seven years he is better able to articulate simple representations. He now can construct more complicated images and more elaborate concepts.

Nevertheless, his understanding of a concept is still based on the perceptual aspect of the stimulus. As an example, at the age of four years the child thinks that beads in a tall cylinder jar are greater in quantity than the same number held in a short squat jar. If a round piece of clay is pressed out

onto an elongated cylinder, a child of this age is apt to think that there is more clay in the latter form. From the age of five to seven, however, the child begins to understand that the amount of beads or clay remains constant regardless of changes in the shape of the containers or the clay. Thus the phallic-oedipal child adds thought to his perception and is better able to comprehend his world. This is what Piaget means when he says that the late phallic child develops the capacity of reversibility and conservation.

The manifest content of children's dreams during the early phallic period shows an emphasis on narrations of events with global impressions using concrete simple attributes. Frequently phallic children have difficulty in differentiating between the dream as a private experience and the dream as a shared experience. The phallic-oedipal child is preoccupied with iconic images of monsters and dangerous animals. Death and physical damage are very much present in the dreams. Simple wish fulfillment dreams do occur, but they are far outnumbered by dreams of traumatic experiences.

Play during the phallic-oedipal years shows a great variety of activity. A child tends to play house, puts on adult clothing, and plays the roles of cowboy, doctor, ship captain, jet pilot, and nurse. His play reflects his anxiety about his smallness, with a compensatory fantasy aimed at the denial of the anxiety. The wish is to be big and to do the things that big people do. Dramatic play occurs during this time in many exfoliations. The child's energy, vitality,

and inventiveness are most impressive. Oedipal play is replete with high feelings of triumph, invulnerability, invincibility, and happiness. Their open expression in play is one of the delightful aspects of oedipal play. Fantasies tend to be very rich and dramatic, centering primarily on the theme of "twins" and "family romance." Fairy tales embody many aspects of oedipal development, emphasizing the dynamic themes of this phase of development. *Jack and the Beanstalk* and *Cinderella* are two outstanding examples found in all developed cultures throughout the world.

Relationships with peers change as the child enters the phallic-oedipal years. Until age three his peers were relatively unimportant to him. Reciprocal play was minimal. His contact with children stylistically reflected his learning experiences at home. In the nursery school situation, however, the child discovers that many of the responses that his parents accepted and rewarded prove unacceptable elsewhere and, in fact, may even incur for him shame, punishment, and rejection. This awareness becomes increasingly acute and can bring about changes in his social behavior as he moves into the preschool years. The child goes from solitary to parallel play and then to cooperative play and finally to reciprocal play during the phallic-oedipal years. His play activity is vitally important, not just for the discharge of instinctual drive and motor energy, but also for the practice of new skills and the opportunity to try new roles and modes of behavior.

The phallic-oedipal phase of development is not just a psychosexual period but also an important psychosocial developmental epoch with enormous developmental overlay. For a child to end this phase of development and to resolve the Oedipus complex, he must attain a higher level of maturation both in the cognitive and perceptual spheres and in living and socializing within the family. Psychosocially the main emphasis is on awareness of goals, many of which can be gratified only in play and fantasy. Genital arousal and pleasure are obtainable only through fantasy, masturbation, and sexual exploration.

The boy wants to take over his mother. The girl wants to be like the mother, even though she may resent and denigrate her, in order to take over the father. The boy tries to do in his fantasies what his father can do in everyday life. And this provides a fertile soil for guilty feelings that can undercut the boy's sense of initiative. His guilt is much greater than the shame and doubt he experiences at the anal-muscular stage of development. The girl experiences guilt in her desire to usurp the mother's role, but her principal emotional burden is one of self-disappointment, frustration, shame, and inadequacy. She feels more and more that she is defective, and it is only on her mother that she can cast the blame. As she looks about from her position of injury and inferiority, she sees her father and brothers seemingly in a far superior position. They seem to have more fun, to be capable of more activity, and to be the recipients of more rewards. Before a boy and girl enter

first grade they must have enough initiative left—after their multiple disappointments, shame, and guilt—so they can optimistically start school and commence the stage of industry in the latency years.

For each child the oedipal experience is unique, determined by earlier ego growth and experience, the instinctual and ego development of the phallic period, and interaction with his parents and family; death and illness, the birth of new siblings, and separation experiences are further influences on phallic-oedipal development.

Phallic Erotism

During the phallic-oedipal phase of development libidinal impulses originate in the zone of the penis and clitoris. The vagina at this phase of development has relatively little psychic significance for the little girl. The phallic child now enters a second phase of infantile masturbation. In early infancy there is evidence of phallic excitation and masturbation. In the second phase of infantile masturbation the excitation is to the objects of the Oedipus complex, with the specific aim of penetration and procreation. The erotism of the phallic-oedipal period is clearly different from genital erotism, which appears developmentally only with puberty and its hormonal changes.-Thus phallic impulses during the phallic-oedipal years are impulses to penetrate but not to discharge semen.

Freud viewed the phallic-oedipal phase of development as one stage in the sequence of infantile libidinal development. He viewed the sexuality of the girl as primarily masculine in character, pointing out that the erotogenic zone of the female at this time is located in the clitoris, which is homologous to the masculine genital zone of the glans penis. For both sexes at this developmental phase only the male genital has prominence and primacy.

Associated with phallic primacy is the impulse to knock to pieces, to hit, to press in, to tear open, and to make a bull's-eye. If the child is made sexually knowledgeable by his parents, he is still puzzled in his attempt to understand phallic penetration in intercourse. As a consequence, he falls back on other ideas of sexual contact and pregnancy, ideas that come from his own experience and feelings. His wishes lead him to want to penetrate through the mouth, anus, navel and in some indefinable way to create a baby. The aim of phallic erotism is thus to penetrate and to procreate. The passive aim is to be penetrated and to bear a baby. Thus the passive wishes of the boy make up the negative Oedipus complex, in which the wish to be castrated becomes a necessary condition of being penetrated and is usually fantasied as being anally penetrated. The child's wish to have the phallic zone stimulated by another person is also regarded as a passive phallic aim.

The child attains sexual knowledge through his perceptions and fantasies.,''' At first the child believes there is only one sexual organ—the

penis. But later he must face the perception that the female has no penis. This perception is not acceptable so he disavows it. Later, because of his increasing reality sense, he cannot maintain the belief that there is no perceptual difference between the sexes. Consequently he must elaborate a series of fantasies to account for it. Now the disavowal becomes more sophisticated."' ("She doesn't have a penis now, but it will grow back.") The child may go on to develop neurotic avoidance of the female genital or femininity in general. Normally these upsetting fantasies are repressed at this stage and the child resolves his Oedipus complex. The pervert, however, has no solution to the Oedipus complex. He is stopped between the disavowal of perception and denial through fantasy. Freud states in his paper on splitting of the ego that the pervert is faced with the fact that his mother has no penis. To fill the gap he creates a fetish or a phobia.

Male Phallic Psychosexual Development

Early in the phallic stage the boy becomes aware of anatomical gender differences, and his awareness of the male genitalia furthers his identification with his father, brothers, and male peers. Now he thinks that he can do what his father does. In addition, his view of the father's relationship with the mother is heightened, particularly in his fantasies of the father's lovemaking with the mother. Now the boy wants to exhibit his phallus to his mother and at the same time look at her breasts and genitals. He may request that she go

to the bathroom with him, or he may blatantly exhibit himself at bedtime to his mother. He views his penis as a penetrating instrument and as a source of great pleasure—earlier, as one of several pleasurable body areas and, later, as a special pleasure structure of the body that he has become aware of through masturbation, exhibition, and sex play.

The boy views himself as a little man; his father is his adult rival. The mother becomes the object of all his pleasures, around whom he weaves a not too innocent "romance." The boy at this time tends to be very protective of his mother, imitating his father in many respects. On the other hand, he may downgrade his father or even at times openly attack him verbally. He may try to play games involving the father's role. He is apt to make up stories and fantasies about larger rivals whom he can easily overcome, like *Jack and the Beanstalk.* The boy realizes, however, that the father's size, dominance, and strength make the competition futile. So threatening is the father that he assumes for the little boy an aura of dread and expectant injury. This threat assumes the form of castration anxiety, which ushers in a new developmental theme. This threat can exist only in the child's fantasies and has no real roots in reality. Often enough, however, the boy has sensed the father's annoyance because of his persistent intrusions into the parents' relationship. Then, too, any punishments the father dispenses to his son during this period, for omissions and commissions irrelevant to the boy's phallic wishes, are seen as direct punishments for his phallic impulses. The conflicts centered around

castration eventually lead to the repudiation of the boy's oedipal wishes. The suppression and repression shift the ego's defense organization. Evidence for this developmental pattern is aptly found in the everyday play of children, and as well as in the fantasies, fairy tales, and dreams of this period of development. Furthermore, anthropological studies of totemic animals, children's graphic productions, data from child analysis, and psychoanalytic reconstructive data are also supportive of these developmental facts.

When the mother indicates to the boy her unwillingness to respond to his wishes, he can react to her in a jealous rage, which either gives rise to or reinforces a wish to kill her and to be loved by the father in her place. The negative Oedipus complex also leads to fear of injury and castration because of passive aims. Both negative and positive wishes in the oedipal period, therefore, arouse castration anxiety.

The boy is quite prone to respond to the oedipal situation with fear of castration. There are many determinants to this fear. The erogenous phallus is an object of attention, pleasure, and fantasy. The boy's concern with uncontrollable phallic tumescence gives rise to his fears that his fantasies will be exposed to his parents. When he discovers the female genitalia, he concludes that the girl has lost her penis. Direct and indirect threats of punishment from either the father or the mother reinforce the fantasy that he, too, may lose his penis. In addition, his earlier experience of losing the breast

in weaning and in losing feces in defecation are preoedipal antecedents to body loss and castration anxiety. The fantasy of castration involves loss of the penis and not necessarily the testicles. The fantasy is based on his view of loss of body part going back to his previous stage of development, where loss of the fecal "stick" suggested a body loss. The boy's castration anxiety is further manifested by overt concern with the body, excessive fear of injury, phobias, and nightmares. The boy must resolve his oedipal conflict by renouncing his wishes and by holding them in check through superego controls, available defensive mechanisms, and ego techniques for resolution of conflict. The boy relinquishes the libidinal object and replaces it by identification with the mother. There is also an intensification of the identification with the father. Identification with the father strengthens the masculinity of the boy's character. The boy's libidinal wishes are partly desexualized and sublimated and partly exhibited and transformed into impulses of affection.

Female Phallic Psychosexual Development

The girl's psychosexual development is in several respects more complicated and less well understood than the boy's. Freud initially assumed that sexual development in boys and girls was similar, a view that he changed in his paper, "A Child Is Being Beaten." He later realized that the girl has to change not only her sexual object from the mother to the father but also her erotogenic zone from the clitoris to the vagina. Psychosexually the girl is

much like the boy, starting out with the mother as the main libidinal object. Her earliest erotic fantasies, like the boy's, involve the mother as object. Between the ages of two and three years the girl begins showing a preference for the father. Much like the boy, the girl increasingly masturbates, using the clitoris instead of the penis. It is here that a gender difference in psychosexual development occurs. Her desire to play the man does not flounder on castration fear. It is castration fear that propels the girl toward the Oedipus complex. She blames her mother for the genital difference and seeks out her father in the hope of repairing her body damage and becoming a man. Even though she may become aware in the phallic-oedipal period of her vagina, the clitoris remains the erogenous zone. Later in development, especially during adolescent years, she starts to switch from the clitoris to the vagina as a primary erogenous zone.

Decisive awareness of gender difference occurs when the girl shifts her libidinous strivings from her first object, the mother, to the father in the hope of achieving an adult heterosexual status. Turning from the mother to the father can be abrupt or quite gradual and can involve antagonism and hostility toward the mother. Often the girl catalogues her many complaints against her mother. The shift from the mother to the father occurs at the time when the girl has become aware of anatomical differences between herself and the male. Her first impulse is to repudiate the sexual difference. The fantasy of having been deprived of a penis by the mother furthers her

antagonism toward the mother and increases her fear of more retaliation from the mother. The wish for the penis heightens her interest in her father and brothers. Penis envy expressed as shame, inferiority, jealousy, and rage is most evident at this time. The girl has a passive wish for the father's penis. She then turns to the father as her principal love object. She is soon rebuffed by the father and forced to renounce her oedipal wishes. The girl's feelings of castration—the female castration analogues—are jealousy and a sense of mortification as well as fear of genital injury, partly a consequence of the wish to be penetrated by the father.

The boy discovers his penis and the girl is quickly made aware of her deficiency. Both boys and girls during the phallic-oedipal years evidence marked narcissistic investment in their bodies. The phallic child displays body curiosity. He explores his body, checking every orifice. The body narcissism is manifested not only by preoccupation with body function but also by dread of injury. The slightest injury is regarded by the child as worthy of a band-aid.

The discovery of sex differences means to the boy that the girl has lost her penis.' He is frightened that he, too, may suffer the same fate. He resorts to ego-defensive maneuvers. He may believe that everybody is built like himself. He can try to convince himself that the girl has a penis that is hidden inside her vulva. Or he can believe that the girl's penis will grow back some day. He

can openly exhibit himself as a way of proving that his penis is still there. He can play games in which he hides his penis between his legs and then allows it to pop forth. He can displace to other parts of his body his concern over castration. He can deprecate girls, even trying to hurt them, to further his image of them as injured. His anxiety can lead to increased masturbation aimed at reassuring himself that his penis is still intact. He can threaten other children with castration. He may do this by intimidating children or by actually trying to hurt them.

The girl, on the other hand, can deny the fact that she has no penis. She may feel that the mother took it away from her. She can repress her awareness of anatomical differences until she reaches adolescence. Often phallic girls, even from sophisticated backgrounds, can deny the vagina well into latency years. The phallic child's view of the parents' external genitalia can further intensify castration fears. The boy, in seeing his father's penis, is apt to feel even more inferior. The girl is frightened in seeing her father's penis. She can fear that her wish to touch his penis may come true. Or she can be alarmed by oral fantasies that aim to incorporate the father's penis. The phallic boy, in seeing his mother nude, may fantasize that her penis is inside her pubic hair.

Primal scene experiences are exciting, stimulating, and often very frightening to the phallic child. All children experience at least auditory

primal scenes. Hearing the parents moving about in bed, awareness of the mother's giggles, the father's heavy breathing, and various noises at the time of orgasm are most stimulating to the child's fantasies. The child does not know who is doing what to whom. A number of children also see their parents having intercourse. Visual primal scenes during the toddler years make the child even more vulnerable to primal scenes during the phallic-oedipal period. Whether the child's primal scene is visual or auditory, the child tends to view parental intercourse as an act of aggression or a fact of exclusion.

The phallic child's awareness of the mother's pregnancy is another source of fantasies during this stage of development. The pregnancy stirs up the child's sibling rivalry feelings and forces the child to elaborate his sexual theories of intercourse, pregnancy, and birth.

Preoedipal Sexual Identification with Love Objects and the Negative Oedipus Complex

Both the male and female child have initially an undifferentiated primary identification with the mother. Later the child internalizes parts of both parents.'' At around two to three years the girl imitates the mother and carries out a flirtation with the father. At this time most of the little girl's investment is with the mother. And in this sense the little girl is experiencing her negative oedipal complex. With the first separation and individuation the little girl then proceeds to the positive oedipal complex in which she reaches

out more affirmatively toward the father. She aggressively devalues the mother. For a girl the negative oedipal complex involves transfer of her aggression to the father. She attaches her libidinal drives to the oedipal mother. For the male at age two and three and a half, the identification shifts from the mother to the father. The boy in his negative oedipal feelings remains aggressively attached to the mother and regards her as engulfing, overprotective, and frequently nongiving. If he is able to resolve these feelings, he then makes a switch in his allegiances to the mother and transfers his aggression to the father. The mother is now valued and the father is seen as a competitor.

If the boy's development is to proceed in a phase-specific manner, his affectionate attachment to his father must intensify. He remains aggressively attached to the mother, with whom he identifies. The boy is then in a passive stage in which he subordinates his active wishes for his mother. During the time of the negative oedipal complex there are two possibilities. The boy can have sexual wishes for the father, wanting to put himself in the father's place and to play a passive role. Or the boy is apt to want to supplant the mother and to be loved by the father.

The Oedipus Complex

The Oedipus complex is regarded by Freud as the "cornerstone" of

psychoanalysis. It is the central part of his psychosexual theory of development and is in many respects the phenomenological core of his theories of infantile sexuality. Rutter's critique of infantile sexuality, for instance, reviews the empirical data that support many of Freud's phallic-oedipal formulations.

The developmental trends that lead to the Oedipus complex involve the child's obligatory dependency on his parents and the child's need to be loved by and to love his parents— the first love objects. The Oedipus complex is a triadic developmental family phenomenon, involving the child's sexual strivings that bring him face to face with his erotic feelings and phallic wishes toward the parent of the opposite sex. The desire for both affection and stimulation from the contrasexual parent pushes the child into a competitive relationship with the isosexual parent. For the boy this results in fear of castration. For the girl this intensifies her antagonism to the mother, her wish to have a romance with her father, be like her father, and be part of the male world. The Oedipus complex is an apprenticeship for heterosexuality and a necessary developmental stage for male and female psychosexual identity. The boy's Oedipus complex develops out of the phase of phallic sexuality. Under the influence of castration anxiety he is compelled to abandon the Oedipal feelings at about the age of five or six, thereby repressing and sublimating his incestuous wishes and further identifying with his father. Castration anxiety, therefore, terminates the oedipal complex in boys. The

little girl, however, must shift from the first object, the mother, to the father. This development occurs when she notices genital anatomical differences. She feels antagonistic and hostile toward her mother. Her first impulse is to repudiate the genital difference by attempting a masculine identification with the father. She masturbates more, with fantasies of having a penis. Because of guilt, however, she may give up masturbation for a while; or, on the other hand, her wish for possession of the father's penis may be strengthened. Rage and despair intensify the little girl's rivalry with the mother. She further turns to the father as her principal love object. She is then rebuffed in one way or another by her father, so that she must now renunciate and repress these oedipal wishes the best she can. She may attempt to remain a "pal" of the father, wanting to do things with him, particularly if she is competitive with her brother. In passing through the "tomboy" stage, she furthers her masculine identification with the father. The shift back to the mother only occurs during adolescence. Frequently, however, the shift is not completely made until the girl has married and has had a child of her own. Since no castration threat can make the girl relinquish her father, the girl's oedipal conflict is not resolved until adolescence or adulthood.

Freud viewed the infantile neurosis as a universal phenomenon in man's progression through the phallic-oedipal phase—apparent for a short time and manifest as a childhood neurotic disturbance, or not apparent at all, sometimes later appearing as neurotic symptoms in adulthood. Freud related

the infantile neurosis to the Oedipus complex. Nagera has reviewed the concept of infantile neurosis from the developmental standpoint. His view is that "the infantile neurosis is ... an attempt to organize all the previous and perhaps manifold neurotic conflicts and developmental shortcomings with all the conflicts typical of the Phallic-Oedipal phase, into a single organization . . . into a single unit of the highest economic significance. ... For these reasons— the 'Phallic-Oedipal' phase is in fact an essential turning point in human development." The infantile neurosis is the first form of neurosis and can lead, with accretions from latency and adolescent years, to adult neurosis. Anna Freud also emphasizes the necessity for certain developmental steps to have been completed before the infantile neurosis occurs. Early deprivations, absent objects, improper environmental handling, various forms of deprivations, and constitutional deficiencies do not allow for adequate identifications, complete internalizations, and normal structuralization of the personality. Thus the child remains in a preoedipal level of personality organization.

Neo-Freudian Formulations of the Oedipus Complex

Since Freud's formulation of the Oedipus complex, there have been a number of other postulations that take issue with Freud's view, particularly in regard to infantile sexuality.

Adler regarded the oedipal child as a pampered child. He saw the normal attitude of the phallic child as that of an equal interest in the father and mother. While he agreed to the possibility of a boy's overstimulation by the mother, he regarded sexual pleasure as incidental to the quest for power. He saw sexual pleasure as incidental in the boy's quest for power and domination over the mother. For Adler the Oedipus complex is simply one of the many forms of child pampering, and in many respects the child eventually becomes the victim of his own fantasies toward the mother.

Jung saw the Oedipus complex as mainly involving issues of independence and autonomy. He felt that if there is no freedom for the child, the Oedipus complex must inevitably lead to conflict. He introduced the term "Electra complex" to denote the girl's conflict between the fantasized infantile-erotic relationship with the father and her will to power. Failure to achieve more autonomy and the need to return to the relative security of the father are key factors in Jung's view of the Electra complex. Freud rejected Jung's Electra complex because it was meant to "emphasize the analogy between the attitudes of the two sexes." Furthermore, Freud felt that Jung's view added nothing.

Another neo-Freudian formulation of the Oedipus complex was made by Rank, who viewed the complex as the origin and destiny of man. The average person, Rank believed, never really overcame his birth trauma. From the

primal horde came the primal family, the group family, and eventually the matriarchal society. The Oedipus complex, for Rank, became a saga, a sociological phenomenon, a compromise between the wish to have no children and the necessity to renounce one's own immortality in favor of children. The Oedipus complex is a reaction to coercion by the human species, which requires marriage and fatherhood against the individual's will.

Horney attacked Freud's biological view of the Oedipus complex. For her the family relationship is a force in the molding of the matrix of character formation. Anxiety comes from conflict between dependence on the parents and hostile impulses toward them, as well as the need to cling to parents for love and security. She doubted whether sexual wishes toward the parents had any relationship to the child's development.

The rebellion of the son against patriarchal authority is central to Fromm's concept of the Oedipus complex. He does agree with Freud that there arc sexual strivings in children, that the tie to the contrasexual parent is frequently not severed, and that the father-son conflict is characteristic of patriarchal society. But he seriously questioned whether the Oedipus complex is a result of sexual rivalry. Furthermore, Fromm questioned the universality of the Oedipus complex. He pointed to cultures in which there is 110 rivalry and no patriarchal authority. He, too, doubted whether the tie to the mother is primarily sexual; instead, the fixation to the mother is caused by maternal

dominance.

Harry Stack Sullivan also took issue with Freud on the Oedipus complex. He suggested that feelings of familiarity toward the child on the part of the isosexual parent foster an authoritarian attitude that produces resentment and hostility in the child. A parent treats the child of the opposite sex with more consideration because of a sense of the child's strangeness. A parent feels justified in dictating to a child who seems to be like himself. The feelings of strangeness deprive the parent of motives for control of the child's life. Consequently the child is treated more carefully. The freedom from pressure results in the child's feeling greater affection for the contra-sexual parent and being more attracted to this parent.

Another formulation of the Oedipus complex comes from the adaptational view, which rejects infantile sexuality and the libido theory. This view was most strongly espoused by Rado. He suggested an ontogenesis of family relations. In his view parents provide the child with conditions that foster the development of omnipotence. A child delegates these feelings to the parents during the anal-muscular phase of development. A rewarding relationship between the child and the parent generates tender affects and parental idealization. Thus the child's object choice is "learned"; it is not a reflection of inborn instinctual drives and their vicissitudes. The child's first sexual pleasure is from autoerotic manipulations. A subsequent shift to

another object comes only after the child has established an affectionate tie to the mother. Now he has learned that he must share the mother with the father and siblings. This initially intensifies his need for exclusive possession of the mother as a dependency object. Consequently both boys and girls in the family are interested in the mother primarily as the affectionate object. In this sense there is no essential difference in sexual development between the sexes. The striking gender difference is in the attitude of the little girl toward her genital equipment. She attributes cultural privileges of greater masculine freedom in play and assertiveness to the fact that the boy possesses a penis. This is the root of the girl's penis envy, a repressed wish to castrate the boy as a means of resolving her dependency needs.

According to the adaptational view, the boy's clinging to his mother results in overt disapproval from both parents, which then leads to an awareness of the incest taboo. The child's response to parental intimidation is hostility to the father, which must be repressed because of fear of castration. The child must further protect himself by repressing libidinal desires for the mother. As the mother becomes more inaccessible he retreats autoerotically to his own genitals or indulges in sex play with other children. If these activities are not interfered with, the Oedipus complex is resolved initially by substitution of himself through masturbation and later by substitution of nonincestuous objects for his mother. In a society that is sexually inhibited the likelihood of parental intimidation exists. As a consequence all sexual

gratification for the child must be given up. Thus the child falls back on the mother again as a sexual object since the inhibition of his independent executive action forces him to return to earlier dependency attachments. The Oedipus complex is thus perpetuated from one generation to another. Heterosexual objects are identified by the boy with the forbidden mother, which heightens his castration anxiety.

In the adaptational view—and this is true also in the classical view of the Oedipus complex—the girl's sexual development is much more complicated and in many respects not as well understood. For the girl the first sexual object is her mother. Later she turns to her father, not, according to the adaptational view, because of sexual differences, but because of subtle persuasion by both the mother and the father. The mother dampens the daughter's sexual interest in herself. She promotes the shift in the little girl's attention to the father through the many examples of her own behavior to the father. As a consequence she helps the girl identify with her, especially if the father sets up no objections. Through his own playful, affectionate attitude toward his daughter he facilitates her identification with the mother. The shift of the daughter to the father is reinforced by the social institutions of our culture, which emphasize attachment to a man as the highest goal for a woman. A contradiction soon arises for the girl. The parents become alarmed at the dramatic shift they have encouraged. Alarm occurs because of sexual overtones in the heightened relationship between the father and daughter,

which then leads to sexual intimidation of the girl in much the same manner that this occurs for the boy. The little girl is now aware of genital differences. She unconsciously attributes her lack of a penis to castration by the mother because of her oedipal strivings toward the father.

In the adaptational formulation castration anxiety for the boy and the girl occurs after parental intimidation. It is not in any respect related to discovery of genital differences. The sexual development of the girl then proceeds in the same manner as that of the boy. This view challenges the view that castration anxiety ends the Oedipus complex in boys but initiates it in girls. In the adaptational view the relationship of castration anxiety is the same for both sexes. It sets in motion repression of the Oedipus complex. In addition, sexual inhibition for the woman is further enhanced by social institutions that limit the woman's freedom in her female role. The woman must present herself as virtuous, chaste, and dimly interested in intercourse. This view facilitates her repression of her sexuality. Her penis envy is exaggerated by the various contrapuntal cultural attitudes between men and women. Intercourse is viewed as an instrument in the battle for dominance-submission. Because of her position vis-a-vis man and society, she is vulnerable to injury; she can only assuage injury fantasies by reparative fantasies aimed at taking over the man's penis. Her sense of male hostility and retaliation is augmented by these reparative fantasies. In addition, penetration by the penis arouses repressed oedipal strivings and connected

feelings of guilt and punishment by the mother, thereby adding another increment of retaliatory fear for the woman. Consequently the woman withdraws from men and is forced to deny her sexual yearnings for pleasure and comfort.

The Resolution of the Oedipus Complex

In the dissolution of the Oedipus complex there occur changes in the aims and objects of the instinctual drives. Progressive modification of the relationship with past objects (parents and siblings) is seen. Anaclitic and erotic aspects of objects are dissociated. Development of new object relations, free of the incest taboo, takes place. Further sexual differentiation occurs. Object cathexis is given up and is replaced by identification with the authority of the father introjected into the ego as the authority of the superego, perpetuating the incest taboo and preventing the ego from returning to libidinal object cathexis. The libidinal components of the Oedipus complex are desexualized and sublimated; in part they are inhibited in their aim and transmuted into impulses of affection. Freud saw the process as more than repression—"destruction and an abolition of the complex." "In boys . . . the complex is not simply repressed, it is literally smashed to pieces by the shock of the threatened castration. Its libidinal cathexis are abundant, desexualized and in part sublimated; its objects are incorporated into the ego, where they form the nucleus of the superego. ... In normal, or, it is better to say, in ideal

eases, the Oedipus complex exists no longer, even in the unconscious; the superego has become its heir." In the *Ego and the Id* Freud, in discussing the loss of the love object resulting in a "setting up of the object in the ego," further comments about the dissolution of the Oedipus complex: "The broad general outcome of the sexual phase dominated by the Oedipus complex may, therefore, be taken to be the forming of a precipitate in the ego, consisting of these two identifications in some way united with each other. This modification . . . confronts the other contents of the ego as the ego-ideal or superego."

The destruction of the child's phallic-genital organization results from the threat of castration and the experience of painful disappointments. The castration threat is in large part the result of the child's use of the mechanism of projection, but it is further strengthened by overt or covert punishment for masturbation and sex play and the boy's observation of sexual differences. When the child abandons the Oedipus complex, his identification with the father maintains the object relationship to the mother that has been linked to the positive Oedipus complex and at the same time replaces the object relationship to the father that has been part of the negative Oedipus complex. The same intrapsychic events take place in connection with the mother identification. Freud feels that the relative intensity of the two identifications is related to the preponderance of one or other of the two sexual dispositions. With the abandonment of sexual aims and the change of object cathexis into

identifications, there results a sublimation that permits diffusion of the libidinal and aggressive components of the object cathexis. This freed aggression helps in the formation of the superego.

Because of the gender differences in the resolution of the Oedipus complex, Freud thought that the superego formation was quite different for the girl. Fear of castration plays no part in the breakup of the infantile genital organization for the girl. For the girl threats of loss of love threaten the Oedipus complex, but what eventually abolishes the Oedipus complex is her increasing awareness through later development that her wish to have a child from the father can never be fulfilled. As a consequence the woman's "superego is never so inexorable, so impersonal, so independent of its emotional origins as we require it to be in men."

Jacobson has analyzed the development of the superego from its earliest precursors to the superego consolidation at the end of adolescence. She has delineated the various types of self and object representations as they take part in the formation of the superego, as well as the role of superego introjection and ego identifications and their relationship to development and experience. Sandler" has developed these concepts further in his concept of the "representational world." The ego establishes the representational world, the center of which is the self-representation, an amalgam of integrated self-images, surrounded by object representations formed out of a synthesis of

object images. Before the phallic period the superego schema reflects the idealized and desirable qualities of the parents and encourages the child to behave, which gains for the child a feeling of being loved. At this point the superego is a preautonomous schema. It is only with the resolution of the Oedipus complex that introjection of the parents occurs and an autonomous structure is formed. Now the introject can substitute for the real object as a source of narcissistic gratification.

With the resolution of the Oedipus complex the child enters the phase of latency, which phenomenologically commences with the shedding of the first deciduous teeth and is dynamically associated with the resolution of the "family romance" and the diminution in the child's narcissistic preoccupation with his body, its functions and its orifices. Latency extends to the prepubertal growth spate of adolescence. During this time further sexual identification and ego differentiation are perceived. Peer interaction is much more common as the child spends less time with his family. In his relationship with other authoritarian figures, as well as in his relationship with peers, there is a strengthening of superego and ego ideals.

The triadic transaction in the Oedipus complex is not limited to the phallic-oedipal period of development. In adolescence there is a resurgence of many aspects of the Oedipus complex as the adolescent attempts to rework previous developmental issues. And in adulthood oftentimes prior to a son's

marriage there is a resurgence of oedipal feelings on the part of the father vis-a-vis his future daughter-in-law. The same, of course, can occur for the mother in her feelings toward her new son-in-law. Later in life grandparents can experience a return of their rivalrous feelings toward a son-in-law or daughter-in-law after the birth of a grandchild; and toward the end of life, if aging has taken its toll on cognitive control and capacity for instinctual delay, a man may give vent to long repressed oedipal urges through molestation of young girls.

There are many reasons for unsuccessful resolution of the Oedipus complex. If a child has had an unsustaining relationship with two parents or has had multiple deprivations during childhood, these experiences will result in a relative inability to relate to parental objects, with impairment in psychosexual development and sexual identity. As a result fragile control of sexual and aggressive impulses, along with little capacity for pleasure, can ensue. Harlow's primate studies have demonstrated that female infants who are deprived of their mothers grow up to be inadequate mothers. Males deprived of their mothers as infants have difficulty in expressing aggression and sexuality. If rather extreme frustration or extreme overindulgence at the preschool level has occurred, oedipal involvement may be impeded. If the contrasexual parent is removed at the beginning of the child's phallic development and remains absent, the child's contrasexual object relation will be strained. He can become overly attached to the parent of the same sex,

making it more difficult for him to work out a heterosexual object choice. Many times, however, relatives, friends, and older siblings offer other identificatory models. The oedipal outcome also depends on whether the remaining parent takes the child as a symbolic substitute for the lost spouse.

The contrasexual parent can behave in an unduly seductive way toward the child, leading to overstimulation of the child, with intensification of any unresolved Oedipal feelings. Death, illness, injury, or desertion of the parent of the same sex during the oedipal period can foster conflicts since these events coincide with unconscious or thinly disguised aggressive wishes of the child toward the isosexual parent. Because of magical thinking, whereby a wish or fantasy is viewed as tantamount to an act, death or illness of a parent can be viewed by the child as a result of his aggression.

Ideally for the resolution of the Oedipus complex the isosexual parent should be non-punitive, attractive, and strong enough to serve as a model for identification. Second, the contrasexual parent should not be unduly punishing, emotionally unpredictable, or seductive so that the child can place full confidence in objects of the opposite sex. Third, parents should show no indication or rejection of the child's genetic sex. Gender-role behavior should not be obscured by the parents in terms of teaching cross-sex-role responses. Fourth, the child should identify with a satisfactory view of marriage, seeing it as providing pleasure, comfort, and security so that he may subsequently

view marriage as desirable and likely for himself.

Fathers who are harsh and punitive make oedipal resolution more difficult. Struggling with such a father, a boy may feel it necessary to give up all women and to assume a passive, compliant attitude toward his father. He may aspire to be the main object in his father's life and see his mother as a rival. Exaggerated character traits like passivity, compliance, ingratiation, and timidity can result. On the other hand, the boy may overtly identify with the father and develop very aggressive pseudomasculine traits, by way of identification with the aggressor. With such a father the girl can assume a masochistic attitude toward men and regard the penis as a sadistic weapon to be passively accepted. In this situation frigidity is common. If the mother is aggressive and a relatively masculine person and the father is passive and feminine in character, the boy must deal with his aggressive, punitive mother.

His inadequately masculine father cannot help him and cannot provide him with a satisfactory identificatory model. Thus the boy must follow in the father's footsteps in the passive, feminine, masochistic way.

A girl may feel that she was deprived by the mother during her preoedipal development. She may think that her feminine attitude has been depreciated by the mother. Thus she can adopt a rather passive attitude toward the mother, maintaining the mother as an object, depreciating the

father as weak and withholding, and entering into a homosexual relationship later in adolescence. On the other hand, she can assume a maternally protective attitude toward the father and establish strong bonds with him that she is never able fully to relinquish. Sometimes older siblings of the opposite sex provide substitutes for the parents, and the oedipal problems may therefore be displaced onto these siblings. Sibling competition with a much older brother can be intensified by oedipal displacements.

Infantile Sexuality and Behavioral Science Research

The existence of infantile sexuality is thought to be substantiated on the basis of direct observation of children, sexual foreplay, sexual perversions, psychosis, the phenomena of regression, data of child analysis, and psychoanalytic reconstruction of infantile sexual life. Freud has been challenged by many neo-Freudians who view infantile sexuality as of no importance compared to the effects of environmental factors or regard infantile sexuality as a result of pathological family interaction. Regardless of theoretical orientation there is unanimous agreement that further study of infantile sexuality, particularly phallic erotism and the Oedipus complex, must be done. With the marked emphasis, however, on methodology and electronic instrumentation for the study of infancy, the phallic-oedipal period and infantile sexuality in general have been relatively neglected. Children's fantasies, dreams, wishes, and other mental events have been comparatively

ignored by research workers in child development. Castration fears, primal scene experiences, penis envy, birth fantasies, and oedipal and masturbatory fantasies are phallic phenomena that warrant research. In addition, fairy tales and myths provide rich sources of research material. The nature of infantile amnesia is poorly understood, partly because of our ignorance of memory mechanisms in general. Further study of the developmental nuances of the female Oedipus complex and its resolution is needed.--Many of the postulates of infantile sexuality, however, are not easily tested by empirical methods. Controlled research in this area is extremely difficult. Preschool children cannot easily report experiences. The use of play and direct observation can produce very misleading and at times naive results. Play techniques are useful as modes of expression. Translations from play to language are necessary, but frequently distortion results.

Child analytic work offers the most convincing evidence for infantile sexuality. Since the child analyst has the opportunity to observe the child over a period of time, he is able to see the multiple variations and transformations in instinctual drive and ego development that occur throughout development. The evidence from child analysis, however, is not always acceptable if statistical requirements are made.

Neurophysiological speculation attempting to relate orality and sexuality by way of contiguous neural limbic pathways does not at this time

supply a physiological support to psychoanalytic concepts.-The connection of thumb-sucking with masturbation has been questioned by Wolfe, who views rhythmic infant activities as motor discharges rather than as autoerotic movements. And the relevance of penile erections during sleep to infantile sexuality is no longer assumed by sleep researchers. It has been shown that penile erections occur principally during a period of rapid eye movement (REM) and may be merely manifestations of altered metabolic states.

The most useful behavioral science research has been applied to questions of gender role and gender identity. Hampson and Money have identified the variables of sex differentiation. Genetic sex, hormonal sex, gonadal sex, and the morphology of both internal and external reproductive organs are the important variables in sex determination. Studies of pseudohermaphrodites have indicated that psychosexual differentiation takes place as an active process of editing and assimilating experiences that are gender-specific and is reinforced by the individual's genital appearance. The gender-role assignment and early gender learning are the most critical factors in psychosexual differentiation. The sex of assignment, according to Money's research, must be clearly made by the eighteenth month of life in order to avoid psychosexual deviation in later years. The preoedipal process of sex-role determination is thought to be related to some type of early learning. Imprinting, a model taken from animal studies of learning, has been suggested as the possible cognitive activity that occurs at the time of the

toddler stage. It appears that the acquisition of gender role and sexual identity is quite similar to language in that for both there is a critical period of growth. Stoller's research has corroborated much of Money's early work. He points out that gender identity depends in the beginning upon sex assignment and that it is established by the age of two and a half to three years. Gender identity comes from experiential rather than constitutional factors and occurs well before the appearance and resolution of the Oedipus complex. Stoller views this process as leading to the development of core gender identity and feels that biological forces silently augment the formation of identity. Therefore, gender identity is not entirely the result of fixation by conflict, but rather the effect of imprinting upon a passively developing identity at a critical period. Thus castration anxiety, penis envy, and the like change only the quality of gender identity.

Cognitive development plays an important role in sex-role behavior. The child cognitively organizes his social world along role dimensions. This patterning is based on the child's concept of physical things. The social world concept is cognitively organized in terms of universal physical dimensions. The organization of role perception and role learning depends on the child's concepts of his body and his role. The schemata that cement events together include his concepts of the body, of the physical and social world, and of general categories of relationships, including substantiality, causality, space, time, quantity, logical identity, and inclusion. The child develops an

unchangeable sexual identity that has its analogues in his concepts of the invariable identity of physical objects. From the patterning arises a self-categorization as boy or girl that is a basic organizer of sex-role attitude.

There is a paucity of developmental studies on memory in children. These are needed to further our understanding of infantile amnesia. Repression at the phallic-oedipal stage is a countercathexis that impedes release of memory traces into consciousness. But, in addition, memory in childhood is an immature and developing ego function. Memory is not only a function of previous experience and storage of information but also the capacity to organize information and reason. A child classifies experiential data differently from an adult. In all likelihood changes in cognitive ego style in the oedipal phase facilitate repression and allow for amnesia.

Central to the core of the classical formulation of the Oedipus complex is the fear of incest. There are recent family studies of incest but only a meager number of developmental studies of children involved in incest. From both a statistical and clinical standpoint the frequency of incest between mother and son, father and daughter, and between siblings is not known. Incest studies of father-daughter dyads, for instance, are not illuminating.

Freud's concept of the clitoral-vaginal transfer theory has been challenged by Masters' and Johnson's research on the female orgasm.-They

suggest that the female sexual drive is based on clitoral eroticism and that it is impossible to distinguish the vaginal from the clitoral orgasm. No such thing as a vaginal orgasm exists; it is an orgasm of the circum-vaginal venous chambers. In the latent phase there is increasing pelvic congestion with transudation and an increase in sexual desire. Psychosexual excitation increases the vasocongestive reaction during any phase of the menstrual cycle.

In support of their concept of the female orgasm, Masters and Johnson point out that genetic sex at fertilization is potent during the first six weeks through a number of forces. Initially the embryo is female with sexual bipotentiality, which changes to a unipotentiality as the testicular inductance substance forms and leads to the production of androgen between the seventh and twelfth weeks. In the male the "clitoris" becomes the penis. From the crura and bulb emerge the male external genitalia. Thus there is in the very beginning of life a constitutional bisexuality and by the phallic-oedipal phase a bisexuality in terms of identifications and introjects.

Freud's theories of infantile sexuality involve many levels of conceptualization. Fear of bodily injury, preoccupation with bodily functions and integrity, masturbation, behavioral responses to primal scene experience, and transactions of the child vis-a-vis isosexual and contrasexual parents are phenomenological. In his review of normal psychosexual development Rutter

points to a corpus of empirical data that child analysts encounter daily in their work. At another level of observation are dreams, fantasies, and memories, report-able by children through verbal and nonverbal means. At another level of conceptualization are postulates of the libido theory and the theory of object relations.'" It is in this area that child analysts-' can provide data and evidence for the whole field of child development.

Latency: The Middle Childhood Years

When the child enters school he is no longer young. He has entered middle childhood, the latency years, or, in Erikson's terminology, the stage of industry versus inferiority. When the child begins shedding his first deciduous teeth, he enters a period of repressive "calm." Between the dramatic changes of the preschool years, with the resolution of the oedipal situation and the diminution of his narcissistic preoccupation with his body and its various orifices and functions, and the prepubertal growth spurt of adolescence, with the increase in instinctual drives and the environmental confusion of that period, the latency child goes through a great deal of psychosexual and psychocultural development. Between the ages of three and five he is struggling with his oedipal relationships and his competitive dependency position vis-a-vis his siblings and his parents. During this time he lives out a happy illusion of being a miniature adult. From age five to seven, however, he is forced to come to terms with his illusion through the solution

of the family "romance" and through fantasies that substitute for primary objects, as well as through reinforcement of his peer group behavior and through a new vision created by experience outside the boundaries of the home. He becomes aware of his relative position as a child in a world of adults. Perhaps this is part of the force behind the typical jokes and puzzles of latency children, remarks that mock adults' intelligence and for a brief period cast the latency child intellectually alongside the grown-up.

In latency the child is no longer satisfied with just play and make-believe. He identifies with people who know things and suggest to him a sense of competence. The danger that his success is illusive is always present. During the stage of industry, when workmanship is so important, the child forgets most of his earlier experiences. He tries to attenuate his family relations and deny what he wants from them. His past hopes and wishes are now less pressing on him. He turns at this time to tools, objects, and work from which he can win recognition by producing things. He learns with others to do competitive tasks with the idea of finishing things. Unlike the child during the stage of initiative, when the emphasis is on the goal but actually very little is done, the latency child aims at completion. During this time he learns to read and write. In primitive cultures he turns instead to gender-appropriate activities that are essential to the survival of the tribe. In most societies selected adults are designated as the teachers, and systematic instruction is provided.

In middle childhood the differentiation of male and female becomes more complete. Boys are taken away from their homes, given tools, instructed in the techniques of the culture, and encouraged to develop skills and workmanship. But some children in every culture want to retreat to earlier years. They are unable to enjoy the tool situation and often feel inadequacy and despair in regard to tools and skills. The period of inferiority can become overpowering for the child, particularly if his mastery of the preceding stage was not accomplished. Work contributes another step in identity development in that the child learns to do what counts. He has more than glimmerings of the fact that part of what he will be is determined by what he does. If mistrust, shame, and guilt are experienced during growing up, he is more likely to develop a negative image of himself.

Harry Stack Sullivan referred to latency as the juvenile era where the chief problems are competition and compromise; the period emphasizes social confidence. School and playground provide the backdrop for the competitive display. New roles are promoted and the child learns new modes of participating with his peers and adults.

Sex-role identification and differentiation are advanced during latency because of peer group and school activities. Peer interaction enables the child to learn his role in society, obtain some familiarity with associative-cooperative play, develop new patterns of aggression including competition

and mastery, develop the ability to subordinate his individual needs and wishes to the group and to reexamine his values in terms of his peer group. During latency he develops his academic skills, largely those involving numbers and words. There is also a strengthening of superego and ego ideals. The superego authority is introjected as part of the outcome of the oedipal conflict. Now for the first time it is available to assist the ego in controlling id impulses. These developmental issues are precursors to adolescent and adult development. Structures are modified and emended during middle childhood and the adolescent years.

In 1896 Freud referred to latency as the time of transition during which repression, a forerunner of defense, usually takes place. He thought that the period occurs from age eight to ten and is marked by sexual quiescence. The resolution of the Oedipus complex, Freud believed, leads to repression as the typical latency mechanism. Reaction formations, sublimations, and superego development are pivotal to this period. Sexual energy is displaced in its gratification since aims are inhibited. In 1905, however, Freud indicated that latency is from six to ten. He underscored his belief that a sexual quiescence continues during these years until puberty. Sarnoff points out in his review of latency theories that Freud continued to believe that phylogenesis produces the ego functions that permit what we know as latency.

Subsequent theories have characterized latency as a period in which

sexuality is less observable, usually repressed, and most commonly suppressed. Few have continued to believe that latency is a biologically determined period in which drive activity is lessened. Regression to pregenital impulses is commonly seen, more so in boys. The child has to work out new defenses against the pregenital drives. Ego development and the establishment of defenses occur. There is an increase in the prominence of secondary process thinking. The reality principle becomes more firmly established, and positive object relations and identifications are consolidated.

Freud was less interested in latency partly because he felt that most of the personality development had occurred by the time of resolution of the Oedipus complex. He emphasized biological factors as most important in the resolution of the Oedipus complex and considered cultural and educational forces as a secondary importance. Freud's concept of latency led to a falsified understanding of the problems of control, stultified research in this area of development, and cast a pessimistic note on treatment of children during this developmental phase.

Latency is not found in any other mammal; it is unique to man. Chimpanzees do not demonstrate this development. It is thought more and more that latency is a cultural phenomenon. Sexual quiescence is hardly seen in middle childhood. Drive strengths are maintained.--Kinsey's data, as well as those of clinical experience, suggest that sexual experimentation and

curiosity persist. Masturba-tory activities and fantasies and sexually tinged play are quite common during latency. The distinguishing feature of sexuality during latency is that children are much more circumspect and socially aware about sexuality.

Structural development, particularly superego functions, increases at this time so that the child becomes more aware of what is socially acceptable. Those children who are cognitively impaired, such as mentally retarded children, demonstrate that without cognitive control sexuality during latency is very manifest. Furthermore, transcultural studies abundantly indicate that phenomenological aspects of sexuality are determined in large part by the degree of cultural freedom afforded the child.

The Phases of Latency

Since latency covers a period of years, it can only be understood if it is divided into two phases. The first phase is from age six to eight. During this phase repression, suppression, and regression are more apparent. Masturbation is inhibited. The child is greatly involved with himself. The ego can temporarily regress to pregenitality with reaction formations of shame, disgust, and guilt. The superego is extremely strict and feels like a foreign body. In interpersonal relationships the superego is crude and ambivalent, especially toward the isosexual parent. Impulses that must be defended by

the superego intensify the ambivalence. Parents cannot be viewed as sexual objects. Drive discharge is through fantasy. Masturbatory fantasies vary according to the child's fixation points. Masturbatory equivalents, such as nail-biting, scratching, and head banging, sadomasochistic to varying proportions, appear in latency. Compulsive talking with excitement is often part of an active fantasy life, which is the primary means of coping with stress. Castration anxiety can persist for the girl. Defenses against penis envy are usually quite apparent. Secondary process thinking waxes and wanes. Increased contact with reality furthers differentiation of secondary autonomous ego functions.

The later phase, age eight to ten, shows better cognitive functions and reality testing. Sublimation is now more successful. There is less suffering over masturbation. There is more gratification in the external world. Fantasy is less needed for drive discharge and by age eleven is used more for reality planning. The superego is less strict. The child in the second phase of latency shows decreasing omnipotence. Defense and affect are now closer to the ego than impulse. Children begin moving more in gangs without adult supervision. From eight to eleven years children begin to show homosexual and heterosexual curiosity and interest. Girls demonstrate an increasing ability to dramatize their feelings.

Between the ages of six to nine the child has to find out how to get along

with others and how to compete successfully. Initially rules for the child are seen as absolute and unchangeable. The crudeness of the superego stems partly from cognitive immaturity. At the age of nine the child, however, has a concept of reciprocity. He now feels that it is fair to change the rules provided everybody agrees and new rules apply to all. From age eleven to twelve he develops a sense of equity. He gives special concessions to handicapped players in games with his peer group. He is able to realize that another child's needs can be different and has thus transcended his egocentrism. He is able to shift his perspective and to be empathic.

The Ego of Late Latency

At the age of eight the child has a well-developed time perspective. His concept of death as something permanent is attained. He has a sense of trust in the future and a sense of objectivity. He now is capable of some detachment from the narcissistic equation of his self and other objects. He is better able to delay gratification and has some tolerance for frustration. He has realistic, nonmagical perceptions of cause and effect. He now tries to master previous disappointments. He shows initiative in the capacity for taking responsibility. His quest for mastery is apparent in many things that he does. Self-esteem increases and is contingent on mastery of competition and competence. There is an expanding cognitive awareness of the world based on increasing trust, autonomy, initiative, and industry. With this cognitive expansion and shift

toward the peer group, the latency child becomes more involved with his peer relations. He depends on them in part to point out external reality, limit inappropriate impulses, share skills and modes of coping, repair damage to self-esteem, offer social means of lessening tension, and reduce the danger to the balance between excitement and control. Peers remind one another of social goals and gratifications. The group helps to maintain its own controls and to resist seduction or provocation. It shows curiosity and praise for other's accomplishments. Thus the peer group provides an auxiliary ego to the latency child.

Physical Growth

From age six onward there occurs a deceleration of growth during the latency interval. At age six the average child is 46 inches tall and weighs 48 pounds. By the time he is age 12, he is 60 inches tall and weighs from 95 to 100 pounds. Physically boys surpass girls in that they are slightly taller and heavier than girls, stronger, better integrated and coordinated neurologically, and have a faster speed of reaction. The gender differential in growth, however, generally ceases at the time of the pubescent growth spurt when girls become slightly taller than boys and remain so until about the age of fifteen.

School-Peer Group Socialization

The child becomes just another child in the school and neighborhood. He learns new roles and modes of behavior. In play he shares things in associative-cooperative play. There are new patterns of aggressive behavior that lead toward mastery and self-control. In peer groups the child must feel that to subordinate his individual needs and goals to the total group, he must strike a balance between the activities of his parents and those of his peer group. The peer group forces the child to reevaluate his internalized values. His means for coping with aggressive and sexual needs are constantly evaluated by his peer group and his teachers as well as by his parents. Performance is a standard by which the child is now evaluated. Internal shifts and accretions in superego and ego ideals occur, with some reduction in the strictness of the consciencc between eight and ten years.

The partial transfer of parental roles to teachers and organized peer groups affects the school-age child in many ways. He becomes more critical of his parents and invests them with less delegated omnipotence. At times he is disillusioned with them. Generally he perceives them in more realistic terms. On entering school he is confronted with an organized peer group, and at the same time he experiences varying degrees of separation anxiety from his parents. In the absence of parents the child's ambivalence shows its hostile side in the form of aggressive feelings and fantasies toward his parents. His modes of defense against anxiety are now challenged by his ongoing experience with teachers and peers.

The school-age child must be more self-reliant in handling fears. His fears change from concrete symbolic representations such as ghosts, monsters, and animals to more generalized and less symbolic substitutions of his fears of parental rejection and disapproval. Concomitantly he develops more reality-based anxieties, particularly ones around performance. He remains in a vicarious balance between his old magical world and the new world of reality, often shifting back and forth in his cognitive appraisal of himself and the world. The child may defensively regress temporarily to an earlier stage where he can utilize old behavior in the service of emotional conflict. He then further develops reaction formations such as guilt, disgust, and shame against infantile impulses that during this growth period become part of the child's character development.

In his sex-role development the child seeks new models for identification. His parents are not enough since he can do so few of the things adults do. Thus girls tend to idealize prestigious and romantic figures. Yet in their play activities they will often act out the roles of mother and daughter. Boys, on the other hand, are prone to identify with people who have status in society—leaders who are strong and assertive. For both sexes peer group formation occurs on the basis of sex differences. In this respect there is a cleavage between the sexes. Popularity within the peer group depends in large part on the adequacy of the child's sex-typed activities and attitudes. Girls are more obsessive, boys, more compulsive, in keeping with the

assigned, socially acceptable mode of the sex role.

Girls can more easily disguise neurotic traits because of their compliance to school situations and their overall need to display only proper social behavior. As in school, behavioral problems of girls are not as apparent as those of boys in the physician's office.

Models are selected for identification on the basis of the child's own skills and personality traits and the familial and peer group pressure toward the adoption of sex-appropriate roles. For example, a boy who is well coordinated and strong, or assertive and outgoing, will pick an athletic star for his model, more so if the parents indicate their preference and encourage him to develop masculine interests and activities. Pressure from the family varies inversely with social class. In other words, lower-class parents are concrete and more specific about what constitutes culturally sex-appropriate role behavior. Children perceive the masculine role as more aggressive than the feminine role. Both boys and girls view the male as both more competent in problem solving and more fear-inspiring. This dichotomous distinction persists through adulthood, still subject to the cultural variants of social class. One study indicated that by the age of 14 girls esteem aggressive-competitive personality characteristics in males as much as boys do. This fact, among others, has been related to the more negative self-concept that the average girl possesses in our culture.

Sex-appropriate behavior is important in the development of children because it is one of the factors that shapes the attitude of peers toward the child. In addition, many personality traits seem to cluster around the adequacy of the gender role. Male-female dichotomy holds for assertive-aggressive and avoidance-withdrawal behavior. Although the child's fantasies can be at variance with his behavior, career choices are in consonance w'ith gender role. Career choice, however, is a phenomenon of adolescence, but expressed ambitions and aspirations are phenomena of middle childhood. Kagan-has suggested that the most stable aspect of personality development is the sex-role identification, which gives both longitudinal direction and organization to the formation of the self-concept, self-esteem, and body image.

The ease in socialization is determined by the child's acceptance or rejection by the parents. If he is rejected by the parents, he is apt to be fearful on entering school and in seeking out relationships. If rejected by parents, he is apt to be aggressive. A second parental behavioral polarity is restrictiveness versus permissiveness. Restrictive parents frustrate the child's need for autonomy. Patterns of control can deviate in either direction. Domineering parents are apt to foster shyness, inhibition, and apathy in the child. Overprotective parents encourage children to be stubborn and irresponsible. Parental permissiveness tends to produce a more assertive, spontaneous child, often to aggressive proportions. Excessive instinctual

gratification can lead to faulty integration of superego and impulse control. Limits for behavior must be set by the parent so that the child can make his choices and decisions. Complete freedom for the child is now an old-fashioned childrearing concept. Latency children still require consistent guidelines and disciplinary measures as signs of love and interest on the part of parents, particularly from the isosexual parent.

As the child moves from the home-centered world of preschool years, he begins to concentrate on objective reality. The child becomes more interested in knowledge, skills, and activities. He searches for general principles and is fascinated with the new, strange, and distant places and people of the world. New experiences with language enable him to communicate with symbols so that he can generalize and abstract. School is the playground in which new activities and skills are discovered and developed. Play is transformed into work. To a lesser extent, scout activities and organized recreational activities serve the same purposes. Parental teaching is supplemented and new experiences in coping with problems are provided. These socializing activities enable a child to initiate the formation of long-range goals.

The child's behavior in school is in large part a continuum of his behavior in the parent-child relationship. The child's adaptation to school depends on factors other than his emotional organization. Separation anxiety

is a crucial determinant. Specific capabilities and maturational readiness to undertake the essentials of education are important. His position and social class also bear on his school behavior. Lower-class children adjust less readily to school because their parents are less encouraging and the peer group less reinforcing of the positive merits of the school experience. Furthermore, lower-class children are accustomed to immediate gratification. The academic curriculum for the middle-class child does not always suit the child in the lower social class.

The sex of the child is another important factor. Boys are apt to adjust less readily to the school experience because of feminization in teaching. Boys tend to react to women teachers with anxiety and tension. They are more hostile to school. Kagan indicates that if more men were to teach children, particularly in the lower primary grades, boys would be more apt to associate the act of acquiring knowledge with masculinity. For example, boys have far more reading and spelling difficulties than girls.' This has been explained in the past totally on the basis of a psychoneurological differential in brain damage at birth. Psychocultural factors, however, play an important part in this gender differential. Boys look upon the customary activities of kindergarten and first grade as feminine since those classroom activities tend to involve cutting out, pasting, and doing "pretty things." Furthermore, boys are much more comfortable in handling aggressive feelings if they are supervised by male teachers.

The IQ of the latency child can change during the course of his education. Several studies have demonstrated that the correlation between IQ of children obtained from age six to ten is .70. At the Fels Institute 50 per cent of the children studied showed changes over the years, most markedly the boys. The drive to learn increased as the children became more assertive and independent at school. Those girls whose IQ changed over the years were closely attached to their mother with whom they identified and whom they perceived as valuing intellectual achievement. Latency children do not have fully developed cognitive functions until adolescence. When they first enter school, latency children tend to be concrete but less animistic and magical in thinking. Later the latency child begins to perform logical manipulation. At first the manipulation involves concrete objects, but toward the end of late latency deductive processes are available to the child. Piaget has serially documented the various stages in intellectual development, from the concrete to the abstract, during this growth period.

Latency Peer Group Selection, Interaction, and Culture

There is a wide variation in peer group ego ideals and values existing within social classes. A lower-class child may be poorly accepted by his peers if he excels in school. The heroes of the lower-class children are not upper-class authority figures. These children are apt to be more receptive to the "heroes" of the television world. The violence of television has more impact

upon children from the lower social classes, in which there is less anxiety about aggressive behavior and a greater tendency on their part to identify with aggressive models provided in television programs.

Friendship patterns in middle childhood years are principally determined by the personality characteristics of the child. Nonintellectual traits are usually selected. Mutual friends will resemble each other in socioeconomic background and general intellectual level, but not in academic achievement. The accomplishment and status of the parents have no direct bearing on acceptance by the child's peer group. Aggressive boys will seek-out aggressive friends. Friendships are made on the basis of gender grouping. The pattern of the friendships is unstable because mutual interests frequently shift. With increasing age general interests become crystallized and the friendships are more apt to be enduring. The peer group interaction has a very decided socialization function. It has a molding effect on the child's self-image and goals. If the values of the peer group are discordant with those of the child's parents, the child may be much more susceptible to peer influence, especially if the child has not made a strong identification with the parent of the same sex, or if he comes from a home where nurturance has been inadequate. This discordant value selection may also be made more likely if the child is not accepted by his peer group and is forced to seek out the group through compliant behavior.

Playing the games of the culture is most important for the latency child. Games with rules, Piaget's third category of play, come into prominence. Hobbies, halfway between play and work, are selected. Some can lead to ego mastery and a sense of job competence. In general, the latency child plays down his deficiencies, plays up his achievements, plays up to his identificatory models, and tries to play fair with his peers.

Latency has its own special culture with its own rules, games, rhymes, and riddles, from which all grown-ups are scrupulously excluded. Children in middle childhood tell repetitiously the same old jokes. Their rites include obsessive counting, peculiar little superstitions, tongue twisters, and odd collections of objects that serve as talismen. Hobbies commence quite early and frequently are precursors to later work. Coded communications are used in the subsocieties of clubs, packs, and gangs, all of which pride themselves on the group's solidarity and individuality. Play is more realistic and imaginative. Peer groups are meticulously organized and founded on rules, oaths, and clandestine passwords. The rules, however, are made to be broken. The activities of latency groups are devoted more to planning than to actual accomplishment. The goals are primarily the exclusion of those children who do not fit into the special identity of the group. Girls organize their clubs for the express purpose of keeping other girls out and gaining strength to reject masculinity. On the other hand, boys are much more involved with the concrete, such as trips, games, and innumerable projects. Their trading of

collections and prized objects is quite common. Barter is a boy's way of comparing assets and strength.

Pubescence

Pubescence or prepuberty is generally regarded as the two-year interval that precedes the onset of full puberty. In many respects it is psychologically closer to the middle school years. Its onset is marked by a spurt in physical growth. Physical changes take place including both primary and secondary sexual changes. Pubescence can be short-lived, hardly noticed by either the child or the parents. The potentialities for physical growth are suddenly realized, with rapid spurts in height and weight and rapid growth of the arms, legs, and neck; changes in body structure, increased sexual impulses, and growth of the genitals occur. The triggers for pubescence are neuroendocrinological. Both physical and emotional changes are not fully understood. At puberty the biological changes reach a peak marked in the female by menarche and in the male by spermatogenesis. This period of development is often dubbed preadolescence, which is confusing because the term is often used to designate the middle school years as an epoch.

Pubescence should be regarded as part of early adolescence. It is a distinct interval in child development during which instinctual drives increase; sexuality blossoms, and physical growth pushes forward with

breakneck speed. With the intensification of both aggressive and sexual drives, the onset of rapid growth, changing body concepts, and narcissistic body concern, the pubescent child is completing his shift in cognitive function from the concrete to the abstract. Thus, at a time when he is developmentally capable of greater rationality, he is beset with more physical discomfort and emotional uneasiness. Temporary losses in the personality gains made during the middle childhood years often produce a picture of the dissocial or early psychotic adolescent. Regressive trends to both phallic and preoedipal phases are present and frequently ephemerally apparent. In early adolescence attitudes of cleanliness become converted to dirtiness, neatness to disorder, sociability to boorishness; moods swing from euphoria to depression; and there are frequent rumblings and alienation from parents. There occurs a resurgence of dependency and ambivalence, especially in boys. Girls seem to experience less regressive pull in their development at this time.

In general boys are more immature and more apt to regress than their more mature and sophisticated female counterparts. Boys often feel inferior. They fear any trace of femininity in themselves. They are concerned about growth changes, particularly ones involving the genitals. Both boys and girls are very much aware of body hair as an early indication of sexual maturation. Modesty, which was of little importance during the early middle childhood years, now becomes maximally important to shroud the child until he has "arrived."

Physical Changes in Adolescence

Physiological and morphological changes in early adolescence are striking from ages 11 to 15. In the male from age 13 to 15 there occurs a growth spurt. Fourteen inches is maximal growth for boys, the average being about eight. The average boy gains roughly 40 pounds. Between 15 and 18 growth slows down and then ceases. The girl experiences her growth between 11 and 13. Her average gain is five to six inches. Her growth is thus two years earlier than that of the boy. From age 13 to 16 her growth slows down and then ceases. The popular notion that girls mature earlier than boys stems primarily from the fact that girls attain their adult height and weight about two years earlier than boys.

During adolescence body proportions change; this occurs several years later for boys. The "baby phase" of childhood begins to disappear. The forehead becomes higher and wider. The mouth widens and flat lips become fuller. The slightly receding chin of childhood begins to jut out. Relatively large head characteristics of childhood become smaller in proportion to the total body height, due to the fact that during this period the extremities are growing at a faster rate than the head. The reproductive system particularly increases in size, but the brain does not change noticeably during this period. There is a decrease in subcutaneous fat so that the proportion of body weight attributable to fat decreases, more so in boys than in girls. Basic changes in

size, proportion, and shape are most pronounced in the bones. Ossification speeds up and is completed in the female by age 17 and in the male by age 19. There is a marked increase in muscle tissues in relation to total body weight. For the female between age 12 and 15 there is pronounced growth; for the male, between age 15 and 16. Motor performance, coordination, strength, speed, and accuracy in the female improve to age 14, in the male to age 17. Boys in many respects show better motor performance than girls.

Changes in the Reproductive System and Sex Characteristics

In the female the primary sex characteristics involve the genital urinary system. The secondary characteristics appear at age 11, with the development of breast buds usually appearing two years before mcnarche. This is followed by pubic and axillary hair and increased widening and deepening of the pelvis. When ovulation appears two to four years after menstruation, conception becomes possible. For the male primary sex changes occur from 12 to 14. Secondary sex characteristics are initially pubic with later axillary, facial and bodily hair and changes in voice.

The sequence for the male is increasing size of the testicles and scrotum, the appearance of pubic hair from 12 to 14, enlargement of the prostate gland, penile growth, and the occurrence of ejaculation one year after pubic hair. Spermatogenesis takes place between the age 15 and 16 and marks the

beginning of nubility.

Tertiary sex characteristics for the female include a specific infrafemoral angle, arm swing, pelvic tip, and lateral ball throwing. Menarche for the American girl appears on the average at the age of 13. In 1900 the average age was 14. This change is attributable to better health and nutrition. Ninety-seven percent of girls have first menarche between 11 and 15, but the age range is from 9 to 20. The year following the year during which there has been maximal growth in height is frequently the year of onset of menarche.

Menstruation is a maturational crisis for the girl since it is a symbol of sexual maturity. In one study only 6 per cent of teen-age girls indicated any sense of pride in menarche. This predominantly negative attitude is influenced by the attitudes of parents and friends, who foster a negative feminine identification. This is found in other cultures such as Bali where menstruation is responded to with shame. The Manus and Arapesh view menstruation as a result of injury or an indication of dangerous powers. Young girls are apt to view menstruation as equivalent to excretion, loss of control, fear of injury, evidence of genital damage, punishment for masturbation and incestuous desire, an indication of need for surgery, and a precipitant for depression.

Nocturnal emission is the male psychological counterpart to

menstruation. It is equivalent in the sense that it frequently comes as a surprise and is a source of worry to the pubescent boy. Frequently there is minimal information given by parents to teen-age boys. Nocturnal emissions usually occur with erotic dreams. Fischer and Dement have demonstrated that during stage two REM sleep, penile erection occurs. A boy's sense of shame about nocturnal emissions may stem from his fear of instinctual vulnerability and his concern that oedipal wishes will be detected by his parents.

Central Nervous System Development

In puberty neurohumoral stimuli from the hypothalamus result in increased secretion of gonadotropin hormone from the anterior pituitary gland. This leads to gonadal development with increased secretion of sex hormones, both gonadal and adrenal. In females the pituitary produces follicle-stimulating hormones (FSH). In nubility interstitial-cell-stimulating hormones (ICSH) become operative. The remaining follicular cells form corpora lutea. The luteotrophin from the anterior pituitary produces progesterone from the corpus luteum, which prepares the endometrium for implantation. Biological changes have profound influenceonpsychic development. Now there is a genital drive quality to psychic activity.

The psychic changes that take place in adolescence are part of the

second separation-individuation phase, which involves intrapsychic infantile objects rather than the "raw" parental objects of the toddler years. These aspects of adolescence are reviewed in Chapter 18 of this volume.

Chapter 15

Cognitive Development

Jules R. Bemporad

Introduction

For decades the area of cognition was uniformly ignored by psychiatry, which concentrated on the energetic-dynamic model of psychoanalysis or the medically oriented "organic" approach to mental illness. This neglect, in fact, has caused one writer to call cognition the Cinderella of psychiatry. As in the fairy tale, in recent years this neglected Cinderella has indeed been discovered by a number of psychiatric princes and has become a topic of great popularity.

The reasons for this sudden surge of interest in cognition, which for many years had been the domain of somewhat isolated academicians, are many and complex. On a theoretical level the existence of mind has again become fashionable in psychology, and the strict behaviorism that attempted to deal solely with stimulus and response has lost its former prominence. It

can no longer be held as valid that an organism's response is simply determined by an internal copy of a physical stimulus. Any stimulus is cognitively modified, interpreted, and perhaps partially created by the organism, which then selects a response pattern. The ever increasing number of postulated "mediational processes" confirms the need to consider active, selective mental processes between the presented stimulus and the observed response. Similarly the stress on the greater abilities of the ego in psychoanalytic theory has shown that behavior is more than the simple transformation of unconscious drives. The id psychology of early psychoanalysis has been replaced by a theory that makes the ego and its cognitive structures central to the causes of behavior. While some "ego psychologists" such as Hartmann and Rapaport have tried to fit their innovations within the older framework of the energetic "economic" point of view, other psychoanalysts have elaborated core concepts such as identity, the self, and object-relations that are difficult to integrate with classical metapsychology and seem to imply cognitive rather than energetic structural models. Therefore, the importance of the cognitive functions of the mind has reasserted itself in terms of dealing with both external and internal stimulation.

On a more pragmatic level the coming of age of child psychiatry as an independent discipline has directed attention to the developmental process of cognitive growth. The actual observation of children rather than the former

reliance on retrospective accounts of adults has underscored the need for an appreciation of cognitive development to understand the psychic world of childhood as well as the eventual psychic world of the adult. The more children were studied, the more it became apparent that their behavior could not be explained solely on the basis of accumulated S-R habits or on the basis of libidinal stages, but that the development of intellectual faculties, independent of other factors, held an important key to the understanding of childhood.[1] Furthermore, the recent movement of psychiatry into preventive and community mental health brought to light a great number of psychiatric casualties who were lacking in cognitive abilities. The effects of early failure of appropriate cognitive development in the poor and in minority groups mobilized a massive effort at remediation and prevention of these early deprivations.

It is apparent that from the theoretical, academic, and social points of view cognition and its ontogenetic development have become an important area of study in psychiatry. This has been a salutary change since, after all, in studying human behavior we are really studying cognitive processes. The human psyche, whether viewed in terms of repressed memories, current attitudes, or expectations of the future, is made up of cognitive constructs, and, therefore, the alterations and creation of these structures are quite justifiably the province of psychiatry and should be included in a psychiatric textbook, tn the following pages some of the more pertinent issues, as well as

the work of major theorists, in the area of cognitive development will be summarized.

Current Status of Cognitive Developmental Theory

The development of cognitive functions is predominantly viewed as a fluid process, with the emergence of novel capabilities at various steps of ontogenesis. Although the causes for the course of this development are unknown, current theory stresses a phase-specific interplay between innate and environmental factors, with appropriate stimulation needed to elicit or reinforce inborn patterns. There is also a great emphasis on the role of mental activity, of action, rather than simply passive reception of stimulation, as necessary for the growth of cognitive skills. Underlying this view of cognitive development as an evolving progression toward more increasing complexity is the concept of epigenesis, which states that mature abilities at each stage grow out of simpler forms of cognition and that these complex abilities are reliant on the mastery of more primitive tasks. The hallmark of current developmental theory is thus a conception of ontogenesis as a creative process, with the emergence of qualitatively new forms of behavior that require proper environmental stimulation as well as successful completion of earlier adaptations for the process to continue.

As such, most theorists see cognitive development as beginning with

simple innate reaction patterns and passing through various phases to culminate in adult capabilities such as abstract ideas, relative independence from environmental events, and the establishment of self-regulatory systems. At each stage the mind is seen as *actively* structuring a world view, beginning with a primitive logic of action and building on each successive stage to transform its relationship to the environment toward greater autonomy and complexity.

Historical Orientation: Idealism, Empiricism, and Interactionism

In the past theories of cognition usually stressed a specific philosophic position. Plato's doctrine of *Anemnesis* proposed that prior to earthly life the soul had knowledge of ideal forms whose recollection allowed man to structure his phenomenological world. Through development myriad concrete experiences re-evoked the dormant memory of the ideal forms. In modern dress Plato's myth stresses the dependence on predetermined, nonlearned cognitive modes for intellectual development. This idealist tradition thus holds that the sources of knowledge derive from innate structures that are independent of experience. Perhaps the most extreme adherent of this view was the philosopher Leibnitz who conceived of the mind as a "windowless monad" that had no contact with its environment and whose experience was the unfolding of a predetermined program.

At the other extreme empiricists have attempted to demonstrate that knowledge is totally reliant on experience and that cognitive development is the mind's gradual accumulation of sense data. As John Locke proposed, the mind at birth is a *tabula rasa,* a blank tablet, which has no inborn structure or organization, and upon which are imprinted the perceptions of sense data. The empiricist tradition had its greatest popularity in England and France in the eighteenth and nineteenth centuries, perhaps as a result of the impact of scientific methodology and the fascination with technology. Itard, a French educator and psychologist, tried to put empiricist theory to practical use in his attempts to educate the "wild boy" of Aveyron. Itard's two monographs describing his procedures are classics, and his ingenious methods of pedagogy have enormously shaped the current educational practices with defective children. However, Itard's intent was to prove the correctness of the empiricist position, and he extensively quotes Condillac, one of its most extreme adherents. He believed that through proper stimulation he could develop the mind of a boy who had apparently lived alone in the forests of France until puberty. Ultimately Itard's experiment ended in failure: the child never attained the use of language, and Itard concluded that the wild boy had been born defective. It may well be, however, that too many years had passed and that it was too late for linguistic abilities to be formed.

Although the empiricist point of view experienced a revival of interest in this country with the work of Watson and the behaviorists, today few, if

any, theorists would subscribe to either a strict idealism or empiricism in describing cognitive development. It is granted that both innate factors and specific experiences are necessary for the development of intellectual skills. It is less a question of how much is due to innate or learned abilities than how do these two sources of development interact to reinforce each other and optimally combine to exert their maximal effect. Associated problems that arise concern the specificity of eliciting certain capabilities at set stages of development as well as the possibility of reversing the effects of prior deprivation or overstimulation.

D. O. Hebb has approached the problems of cognition from a neurophysiological standpoint and has demonstrated that much of the former controversies between psychologists regarding innate versus learned behavior may ultimately depend on the species of organism that had been studied. For example, insects appear able to perform complex functions immediately after birth, while higher organisms require long periods of nurturance and stimulation before showing even rudimentary forms of adult behavior. In primates and humans Hebb speculates that there occur two forms of learning. The first form utilizes a haphazard trial-and-error strategy and can be observed in very young children or in more mature organisms that were deprived of specific stimulation (such as children born with congenital cataracts or monkeys raised in total darkness). The second type of learning is characterized by insight, rapidity, and flexibility. Hebb comments that higher

organisms that show this second form of learning also demonstrate a prolonged and less effective form of the primary type. It seems that as we go up the phylogenetic scale, there is an increase of type two learning but also that type one learning takes longer and longer. For example, a rat reared in darkness may require 15 minutes to an hour to learn a visual task after removal from deprivation; for a chimpanzee the time required to learn an analogous task may be weeks or months. Hebb attempts to explain this difference in terms of neuroanatomy, dividing the cortex into primary sensorimotor areas, which record external stimulation, and association areas, which combine and integrate these sense data. Through phylogenesis there is a gradual increase in the amount of association areas in comparison to sensorimotor areas, a relationship that Hebb calls the A/S ratio. Species with low A/S ratios show rapid primary learning since sensorimotor sequences are easily established because there is a paucity of association fibers to be organized. However, this same lack of association areas limits the amount of flexibility of behavior after the connections have been established. In contrast, organisms with high A/S ratios require a great deal of time for stimuli to organize the massive association areas. However, once this is accomplished the complexity of the connections allows for versatility of response as well as relative independence from the immediate situational stimulus.[2] The early stage of primary learning is still of paramount importance for higher organisms since it is during this period that the

association areas are structured and thus cognitive relationships may be formed that persist throughout life. This aspect of Hebb's work strongly emphasizes the importance of early experience in all later behavior. In later writings Hebb seems to view the plasticity of the very young nervous system as so great that it is difficult to differentiate innate from learned behavior. Some support for Hebb's theories has come from Sapir's and Whorf's studies in comparative linguistics showing that the structure of the language learned in childhood influences adult cognitive patterns.

Hebb's work is closely related to what has been termed "critical period" theory, which also attempts to deal with the manner of organism-environment interaction, stressing that there are "critical times" for certain behaviors to be learned or for specific stimulation to have its maximal effect. Critical period theory evolved from the field of ethology with the early experiments of Lorenz with newly hatched geese and partridges. He found that although these chicks would normally follow their mother in normal development, they would learn to follow him if he presented himself first. This strong bond continued through maturation so that Lorenz speculated that as a result of this one-time presentation, his image had been "imprinted" in the chicks. Later experiments by Hess showed that there were peak times for imprinting to occur and that after a certain amount of maturation imprinting could no longer be elicited. Scott's work with puppies showed that even in higher species there were optimal times for the formation of an

emotional bond to a trainer. These studies again point to the hypothesis that early experiences or the deprivation of such experiences may have a profound effect on future development.

Harlow's work with rhesus monkeys showed that subjects raised without adequate mothering became sexually inadequate as adults and that the females were incapable of maternal behavior. Harlow found that monkeys raised in isolation for two years were grossly abnormal in play, defensive, and sexual behavior; those raised in isolation for six months were able to develop some play behavior; while those who returned to a natural setting after 80 days of age showed an almost total reversal of the isolation effects. There appeared to be a "critical period" time after which compensatory stimulation was ineffective.

Similar conclusions have been reached in work with deprived infants. Rene Spitz found that infants who were separated from their mothers at six months of age and were not provided with an adequate substitute became listless and withdrawn, were retarded in their motor and intellectual development, and were prone to infectious disease. Spitz found that the effects of maternal deprivation were reversible only up to a period of three months, after which reunion with the mother did not completely nullify the effects of separation. Dennis and Najarian" came to similar conclusions following their studies of institutionalized children, although they interpreted

the eventual developmental defects as a result of stimulus deprivation rather than the absence of mothering. Similarly Province and Lipton found that institutionalized children showed significant delay in smiling responses, handling of toys, speech development as well as interpersonal relations. In follow-up studies Goldfarb found that children who were placed in foster homes had higher IQs than children who remained in institutions.

The pressing questions raised by critical period theory are whether the effects of early stimulus deprivation are irreversible or if later remediation can be compensatory. Scott believes that "organization inhibits reorganization," indicating that once patterns of cognitive and affective experience have been formed, it is difficult, if not impossible, to impose new patterns. Counterarguments are that most of the evidence for critical periods has been in lower species, which, as described by Hebb, have little capacity for complex neuronal interconnections in the association areas and possibly are thus less able to modify past learned behavior. Also most critical periods studied involve formation of affective rather than cognitive functions. The lack of hard evidence for the existence of critical periods in human cognitive development has caused Wolff to criticize strongly the application of this formulation to child development, especially in the form of educational gadgets or "enrichment" toys that are promoted as necessary for proper intellectual growth. Wolff believes that the greater complexity of the human brain makes feasible much more flexibility than critical period theory allows.

He believes there are optimal periods for the attainment of certain abilities such as the learning of a second language, but that on the whole the human mind can make compensations that are beyond lower species. In support of his argument he quotes recent stud- ies that seem to indicate that the effects of early deprivation are not as irreversible as previously thought. Another important point raised by Wolff is that there is little agreement about what critical periods exist in human cognitive development. Retardation may result from lack of stimulation or novelty, but it may also be a product of overstimulation and unpredictability, which prevents the child from assimilating his experience into meaningful categories. Finally the social milieu may actively discourage exploration or fantasy, negatively rewarding attempts to integrate and master experiences. Many of Wolff's arguments reflect the current controversy surrounding Head Start programs. Culturally disadvantaged children repeatedly have been shown to be deficient in language skills and abstract ability; however, the cause as well as the best methods for remediation are still hypothetical.

Cynthia Deutsch has stressed difficulties in learning auditory discrimination as basic to later language disorders. The child is surrounded by meaningless "noise" with little meaningful auditory stimulation, so he does not develop the ability to identify nuances of sound.[3] Fineman stresses the importance of mother-infant interplay in the development of an active inner fantasy life and ultimate cognitive ability. Pavenstedt emphasizes the need for

emotional tranquility and regularity for any learning to take place.

Most remedial programs have found that intervention before age three is crucial, some suggesting that compensatory tutoring should begin prior to 14 months of age. These findings reinforce the concept of epigenesis that unless early cognitive tasks are properly mastered, later development will be deficient. However, positive care during the first three years does not insure continued development; proper support and stimulation must continue throughout childhood. In fact, most of the gains made by Head Start programs have been rapidly lost once these programs were discontinued. The difficulties that beset attempts to specify the causes of deficient cognitive development in disadvantaged children may serve as illustrative to the field of cognitive development in general.

The development of cognitive functions cannot be divorced from emotional factors such as a healthy mother-infant relationship in the early years, respect for autonomy and curiosity during early childhood, parental motivation and models during middle childhood, and the effect of peer pressure in the later stages. As systems of cognitive growth will be discussed below, it is important to keep in mind that such descriptions are really artificial since the development of intellectual functions cannot be separated from the total growth of the child. Recent studies have shown that children learn predominantly through action, that sensory stimulation by itself is

insufficient unless it elicits a motor response that alters the environmental situation. There is a unity between stimulation, response, and alteration of the stimuli in the growth of behavior. Numerous experiments by Held and others have shown that proper "stimulation" involves a process of motor response and resultant sensory feedback—a sequence that Held calls "reafference." A typical study involved a series of two kittens raised in darkness, but regularly placed in a circular drum whose interior was painted with vertical lines. One kitten was strapped to a harness connected to a central axis in the middle of the drum, but it was free to exercise. The other kitten was placed in a gondola directly opposite the "active" kitten, but it was unable to exercise. Each time the active kitten moved, he caused the "passive" kitten to be passively moved by a bar connecting the kittens. In this manner both kittens were exposed to the same stimulation. After an average of 30 hours in the apparatus the active member of each pair showed normal visual behavior in terms of averting collision with objects, not going off a "visual cliff," and so forth. After the same period the passive kitten failed to show these behaviors.

Toward a General Concept of Development

The preceding section has considered the sources of development as well as the question of interaction between maturation and environmental effects for optimal cognitive development. However, what is actually meant

by "development?" It is well known that a 15 year old can perform mental tasks that are beyond the capacity of an 8 year old, who, in turn, can utilize concepts unavailable to a 2 year old. However, when a definition of what lies behind these obvious changes is sought, great difficulties are encountered. It appears easier to document static levels of achievement at different ages than to grapple with what is being altered in development. For example, most "intelligence tests" are based on purely empirical standardizations of certain given problems at various ages. These tests may give us evidence of the deviation of cognitive development from a standardized norm, but they offer little in terms of theory beyond the known fact that certain abilities increase with age.

Attempts to grasp *the essence of development,* its formal structure, rather than to document it, have come not from the fields of education or psychological measurement but rather have been spurred by the application of Darwinian evolutionary concepts to ontogenesis. One of the earliest and best known of these attempts is G. Stanley Hall's recapitulation theory. Hall speculated that human development presents in a condensed form all of the stages through which the species had traversed in evolution. The behavior of children could then be seen as atavistic remnants of former evolutionary periods. Hall's theory found its greatest influence in describing the play activities of children: the child's insistence on swinging from branches showed the influence of our simian ancestors just as the pleasure in outdoor

group activities was seen as a vestige of primitive man's tribal existence. A very similar theory was espoused by Thorndike, who saw the behavior of the child as expressing those actions that had allowed the species to survive. Although avoiding Hall's Lamarckian interpretation of evolution, this theory as well neglects the effects of acculturation and seems to equate ontogeny with phylogeny. Today these two processes are seen as similar but far from identical so that the one cannot be used to explain the other, although both may follow analogous laws.

It was toward a discovery and elaboration of these laws of general development that the comparative psychologist Heinz Werner applied himself in a series of articles and his major book, *The Comparative Psychology of Mental Development.* Werner believed that developmental psychology has two basic aims: (1) to grasp the characteristic pattern of each genetic level and the structure particular to it, and (2) to establish the genetic relationship between these levels in respect to the direction of development in order to discover any general tendency in development. Through his work Werner eventually proposed an "orthogenetic principle"' by which he hoped to be able to explain any open system in the process of evolutionary change. Toward the end of his career Werner had even discarded the dimension of time in his consideration of development, basing his studies on increasing complexity of certain factors in discovering the direction of movement for any open system. He thus antedated "general systems theory" and was a pioneer

in the field of theoretical model-building for biological systems. Through this type of analysis Werner tried to encompass the evolution of cultures, the growth of language, the changes observed in psychopathology, as well as the normal development of the individual. In his book, in fact, Werner discusses many important aspects of ethology, anthropology, and psychopathology; however, for our purposes the discussion will exclude these other contributions and concentrate on his theory of human cognitive development. [4]

Werner criticized most psychological theories of development, with the exception of Gestalt psychology, as too mechanistic, considering development as the mere addition of new abilities. For Werner development is creative and organismic, bringing about totally new abilities and radically changing the developing entity. Each new stage represents a totally new organizational synthesis that must be understood through different criteria than previous or later stages. "Any level, however primitive it may be, represents a relatively closed, self-subsisting totality. Conversely, each higher level is fundamentally an innovation, and cannot be gained by merely adding certain characteristics to those determining the preceding level" (p. 22). Werner attempted to find standards by which to compare and measure these differing stages of development. The two major changes that occur in development and that thus could be used to assess it were: (1) that development proceeds from a state of relative globality to a differentiation of parts, and (2) that there is an

increasing integration of these parts into a hierarchical arrangement. Here again it must be stressed that Werner was interested in formulating the formal overall plan of development rather than a detailed descriptive analysis.[5]

In order to measure these two major dimensions, Werner formulated five sets of parameters that he applied to cognitive development. The first, that of *syncretic* versus *discrete* functioning, refers to the interpenetration of functions in the child that become increasingly discrete in the adult. For example, the child often fuses together sensory, motor, and emotional components of experience. Young children exhibit synesthesia or the fusing of two sensory modalities, such as a three-year-old boy, reported by Werner, who stated that "a leaf smells green." This syncretic tendency of a child's thinking was experimentally demonstrated by Wapner at Clark University. Children of increasing age were asked to adjust the speed of a series of pictures moving past an aperture in a board so that these pictures moved at the same speed as another series of pictures moving past another aperture in the same board. In comparing the adjustments made for a static picture (grazing horse) and a dynamic picture (running horse), it was found that younger children increasingly adjusted the dynamic picture series to a slower speed than the static picture series. The dynamic aspects of the presented form were syncretically fused with its actual speed for the younger children so that the running horse series seemed to be moving faster than the grazing

horse series.

A further example of syncretic functioning is given by Werner and Kaplan"' from their studies of linguistics, although their conclusions are equally applicable to child development. In studying the language of the Trobriand Islanders, they found that, in contrast to our own language, a specific word contained many exact yet unconnected meanings. The word "yam," for example, in addition to being an edible type of potato, denotes a specific degree of ripeness, bigness, and roundness. If one of these characteristics is missing, the object is 110 longer a yam—it is something else. Similarly the child infuses an object with a myriad of unessential qualities that to the adult seem separate from the object itself.

An important instance of the child's syncretic fusing of cognitive and emotional modes is expressed in Werner's concept of "physiognomic perception." Werner means that the child ascribes human qualities to all sorts of objects so that they appear animate and express some sort of inner life. A rock may be happy or a hat may be sad. Even adults retain this form of description in such phrases as an angry sea or melancholy sunset. However, while for the adult the imagery is metaphorical, the child actually ascribes feelings to inanimate objects, again fusing qualities that to the adult seem quite discrete. Werner also noted that in pathological states such as brain damage and schizophrenic psychosis there is a regression of formal thought

operations to the syncretic mode.

A second parameter is that of *diffusion* versus *articulation,* indicating the transition from the global perception of wholes to the appreciation of parts in relation to the whole. Werner showed this tendency of young children to omit details and grasp only vague global characteristics by asking them to reproduce geometric figures. A square, as well as the letter "C," was reproduced as a circle, demonstrating a trend toward symmetry and an avoidance of nonglobal characteristics such as corners or breaks in contour. More complex figures were similarly simplified. A more crucial aspect of the diffusion-articulation continuum is the young child's tendency to equate a detail of the whole with the whole itself. Werner reports a boy who was afraid of spiders becoming upset when a hair stuck to his fingers. When the hair was removed the child asked, "Didn't the hair bite you?" showing that he equated qualities (biting) of the whole (spider) with the part (hair). In an analogous manner two situations may be equated if they share an element, however trivial, in common. Another child reported by Werner, who was picked up by an uncle wearing a rose in his lapel, expected to be nursed by the uncle because his wet nurse often wore violets. Here the sight or smell of flowers made the situation of being picked up by uncle identical to being fed by nurse. Again the use of part-symbols to represent wholes is often used by adults in allegorical works, but to the child the identity of the associated situations or objects is real rather than poetic or metaphorical. Werner termed this type of

cognition *pars pro toto* (or part for whole) reasoning. This type of logical association has been subsequently found to occur in adult psychopathological states; in addition, it is similar to processes described by Freud in his interpretation of normal dreams. As will be described below, Arieti has discussed the same process as fundamental to "paleologic thought" and Piaget has coined the term "transduction" to describe association of wholes by their similar parts.

The remaining three parameters can be dealt with more briefly. The *indefinite-definite* continuum refers to the organization of goal-directed behavior and the ability to withstand desires to give way to momentary gratifications. The *rigid-flexible* continuum describes the transition from fixed, stereotyped responses to the ability to vary or modify behavior to meet the needs of a situation. Finally the *labile-stable* continuum refers to the distractibility of the child by external stimuli in contrast to adult behavior, which is characterized by persistence to a task despite environmental interruptions.

It is apparent from this very brief resume of Werner's system that he was more concerned with formulating laws of development than in describing various developmental stages and in stating broad principles than in noting the abilities of children at various ages. His experiments and illustrations serve primarily to confirm his general hypothesis: that

development is a fluid, evolving process that can be assessed by specific parameters. Wapner, who worked with Werner on numerous studies, has recently tried to postulate a series of stages of development as derived from the "organismic" point of view. Wapner describes four major stages in the cognitive development of the child. The first is the *biological-organismic* level, in which there is minimal separation of the self from the environment, physiological intraorganism mechanisms predominate, and behavior consists largely of innate reflexes. The next state is the *sensorimotor* level, characterized by a separation of the self from the environment and the willful manipulation of objects. The third stage is the *perceptual operations* level, in which thought and behavior are dominated by the most striking perceptual elements in the environment. The last stage is the *conceptual operations* level, in which behavior is a result of symbolic representations of objects and events rather than pure mirroring of reality. Wapner stresses, as did Werner, that as newer levels are reached, the older cognitive styles are not eliminated but relegated to a lower hierarchical status and that primitive forms of behavior may still emerge in the presence of stress or disease.

Despite these attempts at delineating steps in cognitive development, it must be reemphasized that Werner's major contribution seems to have been in trying to grasp the essence of the developmental process rather than in defining discrete stages. The more painstaking and perhaps thorough task of studying the child's cognitive behavior as it relates to developmental stages

as well as the total process has been more closely actualized by Piaget and his collaborators, whose work will be considered next.

The Genetic Epistemology of Jean Piaget

Theoretical Introduction

Piaget has carefully termed his work "studies in genetic epistemology," emphasizing his concern with the way the individual constructs and organizes his knowledge of the world during his historical development. At each stage of development problems in world construction are handled according to age-appropriate conceptions, with the earlier attempts forming the foundations for later capabilities, culminating in the logical thought of the adult.

Piaget states, "psychologists eventually began to wonder whether the logic was innate or resulted from a gradual development. To solve problems of this kind they turned to the study of the child and in so doing promoted child psychology to the rank of genetic psychology. Genetic psychology becomes an essential tool of explicative analysis to solve the problems of general psychology."

In attempting to derive the adult modes of thought from childhood experience, Piaget shows his basic roots in biology and his great debt to

Darwinian thought. In his later works he acknowledges that our knowledge of reality is not a copy but an organization of the real world. But at the same time this knowledge cannot go beyond our actual experience as human beings enmeshed in nature. He discards any transcendental aspect of truth that goes beyond our biological makeup. Knowledge is seen as a biologically useful ability that regulates the individual's exchanges with the environment, and cognitive functions are conceived of as specialized organ systems that help higher organisms relate to their world.

Piaget specifies three types of intelligence: (1) innate abilities such as instincts; (2) learning that relates to the concrete physical world; and (3) logical mathematical structures that are utilized in nonrepresentational abstractions. Whereas most species are suitably adapted through instinct, in the higher animals there is a breakdown of instinct or hereditary programming in favor of new cognitive self-regulations. These take the forms of "reflective interiorization," meaning the ability to re-create internally segments of experience, and "experimental exteriorization," meaning the ability to vary the course of a behavioral response for maximum benefit. For Piaget, cultural or social interaction takes the place of previously fixed instinctual responses in protecting an organism in its exchange with nature. This Darwinian view of the origins of cognition bears a strong resemblance to the equally evolutionary theory of thought in recent psychoanalytic literature. Hartmann, for example, states that as an organism ascends the phylogenetic

scale, the id becomes increasingly estranged from its reality, giving rise to the need for greater ego functions. For psychoanalysis this estrangement of instinct from nature leads to inescapable problems in biological expression and fulfillment; for Piaget, however, this development of mind does not bring about any psychological disharmony.

The other major difference between Piaget and the classical epistemologists is his emphasis on the role of action in cognition. For Piaget an object is known to the extent that it is acted upon or forms part of an action process. Cognitive functions not only subserve action but also are forms of action themselves. Thinking is not only for action but also is action. What Piaget calls operational thinking is in essence internalized action sequences; thus the early motor action sequences constitute the source of all later cognitive operations. This stress on mind as action and as specifically concerned with solving problems that will insure adequate functioning helps explain Piaget's notion of the nature of intelligence and of some of the driving forces in cognitive growth. This view of thought as internalized action shows Piaget's roots in pragmatism and ultimately his seeming disinterest of the richness of inner life.

Growth as Sequential Equilibration

Piaget broadly equates intelligence with biological adaptation, which he

sees as more complex than simply survival or the establishment equilibrium between organism and environment. Adaptation is a process involving the reciprocal sequences of assimilation and accommodation. By assimilation is meant the process whereby "reality data are treated or modified in such a way as to become incorporated into the structure of the subject." The environment is grasped or reacted to only if it can be fitted or transformed into the existing mental capabilities of the subject. For Piaget "intelligence is assimilation to the extent that it incorporates all the given data of experience within its framework." The corollary process, accommodation, occurs when alterations in the environment cause the organism to broaden its mental framework so as to integrate the new data. Rather than altering or misperceiving the stimulus to fit pre-existing cognitive modes, the organism must modify itself to deal with this new experience. Each process is never pure since each assimilation introduces some new element that causes accommodation; and each accommodation, by creating new mental schemes, sets the stage for more sophisticated assimilation. It is this interplay between assimilation and accommodation that describes the progressive enlargement and development of mental structures or schemes. At each stage of mental development there is a constant sequential balance between the two processes. It is important to note Piaget's stress on the reciprocity of stimulus and response. The cyclic process can be found in all stages of development, from the neonate's spontaneous movements and reflexes to the adult's

abstract formulations.

Although the equilibration of assimilation and accommodation are used to describe development, these are not the forces that cause cognitive growth; rather Piaget delineates four general factors that are important causes for mental development. The first factor is organic growth or maturation of the nervous and endocrine systems. A second factor is the role of exercise and acquired experience from action performed upon physical objects. This area of development relates directly to firsthand experience with the routine physical world. The third factor is social interaction and transmission. The fourth factor is an inherent striving toward equilibrium or self-regulation. This last factor is as far as Piaget seems willing to go in favor of any pre-established or teleological view of development. He quite specifically states, "in the development of the child there is no pre-established plan but a gradual evolution in which each innovation is dependent on the previous one."

The Stages of Cognitive Development

Through the interlocking processes of assimilation and accommodation there is a progressive evolution in the mental structures that are utilized to adapt successfully to the environment. Piaget's experimental effort has been to investigate and describe the schemes or modes of mental organization at various stages of development. This goal helps explain his most frequently

used experimental method called the "clinical method," in which children of various ages are asked to perform the same or similar tasks. Following the presentation of a task the child is asked about his understanding of his performance. Piaget is not so interested in the result of the child's behavior as in the types of mental procedure that underlie the child's performance at various stages of ontogenesis. Through these investigations Piaget has been able to document a series of stages that describe the major cognitive modes of childhood. What changes during development are the mental schemes, the mode of organizing and constructing experience.

The earlier or more primitive schemes are concerned with action per se without ideational representation; they are characteristic of the sensorimotor period that extends from birth to roughly 24 months of age. Although behavior during this period is essentially devoid of any conceptual representation of the external environment, the behavior is generally adaptive and therefore "intelligent." At first the sensorimotor level is characterized by reflexes, which, however, should not be conceived of as pure automatism, but as requiring exercise for their continued usage and development. Thus after a few days the newborn "nurses with more and more assurance and finds the nipple more easily when it has slipped out of his mouth than at the time of his first attempts." This stage of reflexes gives rise to the stage of acquired habits. The infant begins coordinating vision and prehension; that is, the child begins to manipulate freely objects in his visual

field. This ability to act upon environmental objects initiates what J. M. Baldwin had called a "circular reaction," which implies the eliciting of a stimulus from the environment as a result of the infant's behavior, which, in turn, tends to affect further behavior. In this manner the response pattern tends to prolong itself and to stabilize its own existence. Through a positive feedback mechanism a primary circular reaction is the exercise and practice of innate reflexes such as thumb-sucking. The secondary circular reaction, however, is more akin to what has been called operant conditioning. The infant's behavior accidentally produces an environmental change that causes a repetition of the act that had fortuitously produced the change. This type of behavior appears around four months of age and ushers in the beginning of intentional adaptations, that is, the beginning of an act in the service of a desire, and with it a gradual differentiation of means and ends. Piaget describes how the child learns to pull a cord in order to cause the shaking of a rattle at this stage. At the same time the child begins to separate internal actions from external results. He begins to form the concept of an external world of permanent objects existing in continuous space. After the age of four months the child begins to react toward a partially hidden object, such as the nipple or a bottle, as he formerly did toward the whole bottle. In the next stage of the sensorimotor level extending from 8 to 12 months, the child is able to utilize his action schemes in new situations to produce novel results and achieve new goals. The schemes have become an instrumental act that

can be applied to varied situations.

There are correspondent advances in the child's concept of an object. At about one year of age the child can search for an object if it is placed behind a barrier. Thus the child has the concept of the permanence of that object that continues to exist even when it is not directly observed. However, if the object is removed from behind one barrier and in full view of the child placed behind a second barrier, the child will continue to search for it behind the first. The child has the idea of object permanence but not of the multiple displacements of the object. It has to exist where it belongs. It is not until a later stage extending from 12 to 18 months of age that the child appears to understand the multiple displacement of objects and to search for the object wherever it was last put. Yet at this stage the child still cannot cope with "invisible" movements. Thus if an object such as a ball is held in a clenched fist, the fist put behind a pillow and out of view of the child, and the ball released behind the pillow, the child will persistently search the hand for the ball, never considering that the ball may have been left behind the pillow. It is only with the last stage of the sensorimotor level of intelligence, extending from 18 to 24 months of age, that the child can conceive of actions that he does not witness directly and thus searches for the ball behind the pillow even though he did not see *it put there.*

The later stages of sensorimotor development are also characterized by

tertiary circular reactions whose central attribute is the invention of new behaviors to achieve desired ends. In the secondary circular reactions the child was able to use established patterns in novel situations. Here the response pattern itself is original. This behavior is similar to trial-and-error learning in which alternate solutions are attempted until the correct one is accidentally stumbled upon. It is important to note that these schemes are not created *de novo* but evolve from acquired habits that, in turn, grew out of innate reactions.

The final stage of the sensorimotor level is marked by the beginning of internal representation, which is the transition to later forms of intelligence. The child is able to find new means, not only by "external or physical groping but also by internalized combinations that culminate in sudden comprehension or insight." There is no longer a need to see objects in order to realize their permanence. The ability to picture objects mentally allows the child to search for them after multiple displacements. This understanding underlies the child's concept of spatial relations. The idea of an object being able to cross a path from multiple fixed positions is basic to seeing space as a continuous medium. At the same time the internal representation of space is necessary for the child to see himself in a space and to be able to follow a continuous map from one position to another. A possible limitation of Piaget's pragmatic view of thought as internalized action sequences is his relative neglect of the importance of internalized images during early childhood. The

works of Melanie Klein and later Arieti have shown the crucial role that internalization of emotionally important personages and events during this stage plays in later life. Similarly, although Piaget has devoted an entire book to the subject of symbolism, he seems to view the symbolic functions of the mind in terms of their use for strategies and not important in their own right, as emphasized by Cassirer and Langer.

In summary, the sensorimotor level traces the development from birth to the beginnings of internalized thought. It shows the evolution of habits from reflexes and trial-and-error behavior, culminating in internalized action schemes that make possible the mental manipulations of objects that are not immediately present. With the advent of true representative cognitive structures, the child is no longer at the stage of sensorimotor behavior, yet, on the other hand, neither is he able to form "operative" schemes, which imply a separation of thought from the immediate aspects of reality. The stage of operational thinking consists of representational actions that are reversible in thought but not necessarily so in reality. Prior to this stage the schemes are "preoperational." They are composed of internalized actions but are still tied to perceptual rather than cognitive criteria.

Another characteristic of the preoperational level is "egocentric" thinking, which should be taken only in its epistemological sense: the child cannot put himself in the place of another person. For example, when asked to

describe the view of a model of mountains from positions other than his own, the child at the preoperational level is unable to describe or to select out a proper perspective of the model other than what he sees from his own position. There is also a similar ascendancy of assimilation over accommodation. The child tends to fit his experience into his own categories rather than to expand these categories to give a more realistic grasp of his environment. This is evidenced by the preoperational child's great use of fantasy in play. The play is unhampered by external rules, which are altered as the situation demands, or by a strict adherence to the realistic nature of objects. These characteristics help explain another aspect of the preoperational level, that of ascribing a willful causality to most physical events. For example, children feel that night comes so that we can go to sleep or that if you put on a raincoat it will rain.

This level of intelligence can further be subdivided into two stages, that of preconceptual thought, which lasts from roughly age two to age four, and that of intuitive thought, which lasts from roughly age four to age seven. The former stage begins with the internalization of action, that is, the conceptual intelligence. The child shows deferred imitation, which gives evidence of the beginnings of this internalized representation. The transition from representation in action to representation in thought is reinforced through symbolic play and through the use of drawing and painting materials. Finally the development of language gives the child the usage of symbols by which to

handle internal images and memories. Through language the child can represent a long chain of action sequences very rapidly (while at the sensorimotor level the child had to follow events without altering their speed). The reasoning of the young child, however, is still concrete and at the same time distorts reality. Piaget describes how the young child forms primitive classes based on particulars of objects that have no essential relevance. As stated above, this process, which Piaget calls transduction, is similar Werner's *pars pro toto* reasoning. The particular of an object is equated with the whole in relating objects. The child has not as yet derived a system of concepts that separates details of objects from their essential nature. This centering on an unessential, although perhaps the most conspicuous, aspect of an object continues into the intuitive phase.

The second phase of preoperational intelligence is characterized by a growing capability of separating thought from action. The child is better able to group objects into classes, but only on a perceptual rather than a cognitive basis. The child has not achieved the primacy of thought over appearance. For example, Piaget presented children with a box containing 20 wooden beads, 18 of which were brown and 2 of which were white. The children were then asked whether a necklace made from the brown beads would be longer, shorter, or equal in length to a necklace made from wooden beads. Children at the intuitive level mostly replied that the brown beads would make the longer necklace. From this and similar experiments Piaget concluded that the child

at this stage is incapable of thinking of two subordinate classes, that is, white and brown beads, at the same time as he is thinking of the whole class, that is, the total number of wooden beads. The child's attention is centered on the preponderance of brown beads in relation to white beads, the most conspicuous property, and he cannot simultaneously switch from the relation of "brown beads to white beads" to the relation of "brown beads to the total number of beads." The child's thought is guided by the perceptual aspect of reality. Children continue to conclude that a brown bead necklace would be longer even after they acknowledge that there are more wooden beads than brown beads. The point is that these two aspects of the same situation cannot be integrated at this level. At the level of concrete operations, stretching from roughly age seven to age eleven, however, the child immediately answers that the wooden bead necklace would be longer because "there are more wooden beads than brown beads." Here the child can simultaneously take into consideration the relation of brown beads to white beads (part to part) and brown beads to wooden beads (part to whole). Piaget asserts that at this later stage the child's thought is "decentered," that is, no longer exclusively focused on the perceptual, and is "reversible," that is, can move back and forth through a logical relational thought sequence.

These principles are also exemplified by Piaget's experiments on conservation. One of these experiments involved an equal amount of liquid in two identical beakers, A-1 and A–2, which the child acknowledged as the

same. The liquid from beaker A-2 was then poured into two smaller beakers, B-1 and B–2, directly in front of the child. The child is then asked if the liquid in the beakers B-1 and B-2 was equal to the amount in the original beaker A-1. Children at the intuitive level of intelligence felt that the quantity of liquid had been altered when poured into the two smaller beakers. Similar alterations in quantity were ascribed to when the liquid was poured into different shape beakers, although here again the liquid was poured directly in view of the child. Piaget concludes that these interpretations are due to the child's lack of the schemes of reversibility and conservation; the child centers on what he sees and cannot disengage his thought from his perceptions so that he can mentally reverse the process and conclude that the amounts of water were originally the same. Because of this perception bound set the child cannot consider two aspects of one situation simultaneously, but can only examine one aspect at the expense of all the others. For example, when the child at this stage is shown a ball of clay that is rolled into a sausage shape, he will say that there is either more clay because the sausage is longer than the ball or less clay because the sausage is thinner than the ball. The child cannot conceive of the ball simultaneously becoming both longer, thus having more clay, and thinner, thus having less clay. It is this ability to attend to two aspects of the environment and to relate them in a coherent fashion that leads to the scheme of conservation and marks the beginning of the operational stage. Similarly with the bead experiment described above, the

child in the preoperational stage cannot conceive that white beads and brown beads equal wooden beads. He is centered on the color and cannot conceptualize the two aspects of color and total number simultaneously.

It is with the onset of the operational period that perceptual appearances no longer predominate over thought processes. In this period thought becomes truly "operational," that is, independent of what is phenomenologically possible. The child can go through action steps in his mind that would be impossible in reality. With this enlargement of perspective or "decentering," the child at seven or eight becomes less egocentric. He can shift rapidly between his own views and the views of others, facilitating communication because there is also less idiosyncratic meaning given to words. There is an overall autonomy of the central cognitive processes from the immediacy of the situation. Thought begins to follow a logical, rather than a haphazard, perceptual structure. The child forms the schemes of reversibility and conservation despite perceptual evidence to the contrary. The schemes are seen to go from a quasi-logical order of groupings to a higher hierarchical level of classes.

Yet during the first part of the operational period children can only reason in this manner when they are actually manipulating concrete objects. Their abilities are not revealed on a verbal or nonrepresentational task. A child who can easily arrange a series of dolls according to height and match

the dolls to different size sticks either in a progressive or reverse order cannot as yet answer questions such as "Jane is lighter than Nancy. Jane is darker than Lois. Who is the darkest of the three?" The child can reason independently of perceptual influences, but only when the elements of his cognitive behavior are concretely present. Thus the first part of the operational period is called that of concrete operations. To quote Piaget,'" "The concrete operations relate directly to objects and to groups of objects (classes), to the relations between objects and the counting of objects. Thus the logical organization of judgments and arguments is inseparable from their content." The child can only reason with what is palpably before him. He cannot utilize nonrepresentational abstractions in his cognitive operations. There can be no hypotheses unless the elements of the propositions are directly present in reality. The eventual freeing of thought from content makes the advance to the stage of formal operations possible. In this final stage there is a disconnection of thought from concrete objects so that the mind is capable of dealing with relationships between things rather than with only the things themselves. The preadolescent becomes capable of forming classes according to abstract principles and similarities that defy concrete representation. This "combinatorial system" allows the mind to consider all possible alternatives of any given situation. Some ramifications of this advance are that the adolescent can conceive of the future and plan for it, can think not only about concrete things but also about his own thought.

Furthermore, this ability to consider all alternatives leads to an "experimental spirit." The adolescent, when presented with a problem, takes a preliminary inventory of all the factors and then varies each factor alone, keeping the others constant. At the level of concrete operations the child proceeds directly to action with little attempt at systematization. One of Piaget's and Inhelder's experiments demonstrates the difference between concrete and formal operations quite clearly. They arranged a series of jars of colorless liquids and then showed the child that by adding a few drops from the last jar to an unknown mixture of the liquids a yellow color could be produced. The significant aspect of this problem was that there was no way for the child to figure out ahead of time which mixture of liquids would produce the yellow color once the indicator was added. Inhelder and Piaget then observed the manner by which children tried to combine liquids to arrive at the yellow color. The younger child attacked the problem by adding a few drops from the last jar to each of the others and then felt essentially defeated. From here on he proceeded in no particular order and usually did not think of mixing various liquids and then adding the drop from the last jar. The child at the stage of formal operations, however, solved the problem by systematically going through all combinations of liquids, often keeping notes to be sure that he could keep track of his experimentations. Eventually he not only solved the problem but also identified the different liquids as to their relationships. For example, one jar contained a substance that prevented the

color from appearing. Therefore, in the stage of formal operations the person can generate theories about relationships and derive laws that will explain occurrences in the environment. These laws are not limited to their immediate content and can be applied to analogous events. To quote Piaget, "indeed the essential difference between formal thought and concrete operations is that the latter are centered on reality whereas the former grasps transformations and assimilates reality only in terms of imagined or deduced events.[6]

Summary and Overview of Piaget's System

It will be obvious at this point that Piaget and his associates have derived an enormously rich and complex concept of development, any small segment of which could generate an enormous amount of research and study. However, it is important in reading Piaget to constantly keep in mind his overall system and his epistemological interest. Briefly Piaget believes that cognitive growth is best described as the progressive evolution of the schemes that underlie outward intelligent behavior. At the sensorimotor level schemes are pure action, but gradually this action is internalized into mental representation so that the schemes become truly cognitive. These cognitive schemes progress from representations of the environment to more sophisticated attempts to construct an understanding of the world. During the preoperational phase this construction of reality is haphazard and follows a

loose, disconnected pattern. Objects and events form groupings rather than logical classes and are associated by idiosyncratic or egocentric linkages. The child centers on the most obvious perceptual elements of his environment. This dependence on what can be observed is gradually subsumed under what can be reasoned, exhibiting the supremacy of thought over perception. This decentering allows the mind to follow reason rather than appearance. Piaget thus differs from the Gestalt psychologist's attempt to describe perception and cognition by similar laws. For Piaget these functions are entirely different, with perception being an inferior and more rigid form of behavior. The mind conceives of schemes, such as reversibility, that are impossible in the real world. At first these operations are possible only when directly involved with concrete objects, but eventually operations involving abstract, non- representational forms are evolved. Piaget thus views cognitive development as progressively freeing thought from its concrete surroundings, culminating in abstract schemes that are totally independent of concrete experience. At the same time, however, Piaget remains firmly rooted in biology, stressing that each advance in schemes serves the more pertinent purpose of organismic adaptation. Piaget seems most interested in the mind as a creator of strategies and as the solver of problems. In later years he has devised mathematical-logical models to describe the mind's processes at various stages. As such, he has been less interested in the irrational, poetic, and creative aspects of mind, and his effort has been one of a rigorous

logician.

In recent years there has been a renewed interest in Piaget that might be best described as an explosive revival. Piaget has been discovered, not just by developmental psychologists, but by educators, philosophers, social theorists, and psychoanalysts. Some applications of Piaget's work have been extremely important and interesting. Inhelder has applied some of Piaget's concepts to the diagnosis of mental retardation, which might ultimately culminate in a new system of intelligence testing. Others have used Piaget's experiments to assess the effects of cultural differences. Golden and Sims, for example, found that children of varying social classes did equally well on experiments like Piaget's until two years of age, when lower socioeconomic groups of children began performing much more poorly than higher socioeconomic groups. Wolff has attempted to integrate psychoanalytic findings of object relations with Piaget's work on object constancy in infancy. Odier has utilized much of Piaget's work to show the childhood origins of adult symptoms when extreme anxiety causes a reemergence of prelogical forms of cognition. For example, Odier sees a resemblance between the child's reification of his own feelings and perceptions in believing in their objective reality and the adult's use of projection in pathological states. Similarly Freeman and McGhie have attempted a description of schizophrenic thought according to Piaget's levels of cognitive development, and Anthony has tried to apply some of Piaget's concepts to child psychiatry. Although these

applications have been salutary, Piaget has warned against the overly pragmatic use of theory and what he calls "the American question," meaning the ways by which to speed up intellectual development. Piaget makes a strong point that development has to proceed at its own pace. Too much stimulation or instruction is simply not assimilated and eventually might be harmful.

Finally Piaget seems more interested in theory than in these pragmatic applications. In his summary works he quotes experiments that test other theoretical hypotheses rather than practical aspects of his own work. While much applied, and misapplied, to all sorts of educational and psychological endeavors, Piaget seems to wish to remain in the realm of philosophy and epistemology rather than applied science.

The Psychoanalytic Approach to Cognitive Development

Until recent years the field of cognitive development played a very limited role in psychoanalytic thought. Although certain cognitive concepts have always been a part of psychoanalysis, these have been used mainly in reference to symbolization in symptoms and distortions in dreams." The study of cognitive life as recognized by academic psychologists was considered to be too superficial or too removed from basic motivating forces to exert any real effect on development. In addition, the early years of

psychoanalysis were primarily devoted to the demonstration of the existence of unconscious life, infantile sexuality, and psychic determinism—against massive opposition—so that such topics as cognitive development had to await easier times.

Nevertheless, any system of psychology as far-reaching and comprehensive as psychoanalysis could not entirely ignore cognitive factors, and Freud did attempt to formulate a theory of thinking. According to this model, mental excitation flowed from sensory structures to the motor process that discharged the excitation. Along this basically S-R path memory traces were activated by the excitation, aiding in the choice of discharging action. When, however, the ability to discharge the energy through action was blocked, it reversed its flow back toward the sensory end, resulting in an internal psychic experience rather than action. This model sought to account for dreams, hallucinations, and psychiatric symptoms. The point of this model is that thought or conscious experience occurs when motor discharge of energy is blocked. In a later paper Freud used the same model to account for the mental life of infants and the development of thought. The beginnings of thought or images appear when instinctual satisfaction, and thus the discharge of energy, is not possible because of the lack of a satisfying object. The instinctual energy then activates a memory trace of previous satisfaction as an attempt to partially discharge the energy, and this previous state of satisfaction is hallucinated by the child. Therefore, thought begins as an

attempt at wish fulfillment and follows what Freud called the "pleasure principle." Ultimately, however, the hallucinated satisfaction does not really gratify the instinctual need, and the infant must come to grips with external reality as well as his internal wishes. There is, therefore, a transformation to the "reality principle." However, the mind is always ready, as in dreams or in psychosis, to revert to an hallucinatory world of pleasurable wish fulfillments. Freud's view of mind, his metapsychology, has been repeatedly criticized as being limited by the prevalent scientific modes of thought of his time. This early description of the "psychic apparatus" leans heavily on energetics and resembles the hydrodynamic models of physics popular at the turn of the century.

Eventually, through the evolution of psychoanalytic theory, thought became more than simply an internal agency of wish fulfillment. As a result of revisions brought about by the "structural theory" and ego psychology, the ability to internalize action sequences into thought took on protective aspects and evolutionary significance. The ability to think was seen not just as a way of postponing actual satisfaction and temporarily discharging energy, but as a means of trial action that helped the individual adapt to his environment. Hartmann- especially stressed this pragmatic survival function of thought in psychoanalytic theory emphasizing its adaptive and "conflict- free" functions. Nevertheless, Hartmann attempted to reconcile his "new" view of the ego with the original economic theory of the "psychic apparatus" as an instrument

to reduce tension or energy of the instincts.

Later psychoanalytic thought stated that the ego does not arise out of the id through conflict resolution, but that the ego and its functions develop independently if the environment is adequate. This significant innovation stresses that the ego (and thus cognitive functions) has an autonomous development that unfolds throughout ontogenesis and that development is not contingent on resolution of conflict. Anna Freud has extensively documented various "developmental lines" that trace the path of ego functions through childhood, stressing mastery of such areas as eating, eliminatory functions, body management, as well as relationships to others.

Concomitant with these views on the purpose of thought in ontogeny and phylogeny, Freud postulated two great classes or modes of thought that he called the primary and secondary processes. The primary process was solely concerned with the discharge of energy through any means. Its goal was release of tension or pleasure, and it was not characterized by any strict logical structure. This primacy of instinctual discharge was described in terms of "loosely bound cathexes," which meant mobility and instability. Cognitively this meant that instinctual energy could be displaced onto neutral figures, or that an image could become a composite of many objects (condensation), if this facilitated tension reduction. The primary process was essentially the mode of the unconscious; it manifested itself in dreams, psychosis,

parapraxis, and other symptoms that revealed the true instinctual desires of the individual. On the other hand, the secondary process is characterized by Aristotelian logic and typifies most of our everyday conscious behavior. This secondary process mode of thought is concerned with the individual's relationship to his environment rather than with the release of tension. In terms of development the infant's cognition follows the primary process and his main concern is the attainment of pleasure. Through repeated frustrations, however, the infant learns to cope with the environment, and through the attainment of the reality principle he develops secondary process modes of cognition. This gradual transition from primary to secondary process and the development of ego controls over the biological drives that cannot be expressed because of environmental restrictions have formed the bulk of psychoanalytic studies on the development of cognitive structures in the child. David Rapaport, who was perhaps the psychoanalytic theorist most interested in cognitive theory, stated quite clearly that the major concern of psychoanalytic formulations in the development of cognition was to trace the evolution of ego mastery in the perpetual conflict between satisfaction of internal drives and societal demands. Numerous psychoanalytic studies of child development repeat the theme of ego mastery and view cognitive growth only in the service of this primary aim.

Only in recent years have psychoanalysts turned their attention to cognitive processes as significant in their own right and not simply as better

methods of defense against unconscious drives. One problem that is currently attracting a great deal of attention is the process of internalization of environmental figures and events into intrapsychic structures. Sandler, in a number of articles, has stressed the importance of the "representational world" inside the mind as directing behavior. Schafer, in an important monograph, has tried to refine the vagueness ascribed to terms such as introjection, identification, and incorporation that are commonly used in psychoanalytic parlance. Although these attempts are crucial in directing study to the child's cognitive experience and lessening the emphasis on the pure unfolding of instinctual processes, this area of research is still in its beginning stages and has not as yet arrived at definitive formulations. Other authors who have dealt with topics such as identity formation or the relation of the self to environmental figures without trying to integrate their theories into an energetic model have, on the other hand, refused to classify their concepts as basically cognitive as if this meant a betrayal of psychoanalytic principles.

Another avenue of psychoanalytic study has been the work of Arieti, who has dealt with the development of inner reality and motivational forces from a truly cognitive frame of reference. While praising the psychoanalytic emphasis on inner life, Arieti'' disagrees with its stress on instinctual and biological forces. He believes that the individual is ultimately motivated by higher order concepts such as expectancies of others, demands from the self,

and internalizations of significant others rather than discharge of energy or primitive biological needs. In a recent book Arieti has attempted to describe the development of these inner concepts through ontogenesis. His concern has not been with the child's ability to manipulate the physical environment as much as with the transformation that occurs in intrapsychic life.

He describes the first months of life as dominated by "simple feelings," or "protoemotions," such as tension, appetite, fear, rage, and satisfaction. In general, these protoemotions are global, nonlocalized bodily experiences that are elicited by a stimulus directly present in the environment. These sensations require a minimum of cognitive ability and appear to be the felt components of autonomic reaction patterns.

Toward the end of the first year of life, according to Arieti, the infant begins to retain enduring mental representations of external objects, events, and relationships. The child can create an image—a memory trace that has psychical representation. The image becomes a substitute for the external object and can from then on direct behavior. With the formation of the image inner life truly begins. Cognition can no longer be considered a hierarchy of mechanisms but a psychological content that retains the power to affect its possessor, now and in the future. In contrast to Piaget and some of the stricter learning theorists, Arieti is concerned with the content as well as the processes of the child's psyche. This ability to create lasting internal images

initiates the child into what Arieti calls the *phantasmic stage of inner reality.* This stage is characterized by a higher level of emotional life since the child responds to internal mental constructs as well as to the stimuli of the environment. Arieti calls these feelings "second order emotions" because they are not elicited by immediate, external threats to homeostasis but by the anticipation of such a change; that is, by a mental event that predicts an external event. In this manner purely inner cognitive events begin to alter the life of the child. As early as 1947 Arieti attempted to separate fear and anxiety on a cognitive basis: fear is a primitive reaction to an environmental object, while anxiety results from an anticipated image, that is, from a cognitive construct.

At this stage of development the child also constructs what Arieti has termed the "paleosymbol." By this he means a specific mental concept that represents something that truly exists in reality but whose meaning and value are highly private and personal; the meaning of the paleosymbol is not commonly shared by others. These highly idiosyncratic values given to paleosymbols may account for the young child's seemingly irrational likes or fears of common objects. According to parental handling, neutral objects such as a feeding table or baby stroller can become internally associated with various emotions so that as rudimentary symbols for these objects are internalized, specific meanings are given to their internal representations. For Arieti not only is the creation of symbols in the service of external adaptation,

but also it is essential for the construction of inner life; they become the building blocks for psychic reality. Again there is an important emphasis on inner content and its emotional impact as well as on adaptation to external demands. In addition, however, at this phantasmic stage of development the child has difficulty in clearly distinguishing between internal and external reality. Much of what has only internal meaning is projected or acted out on the environment. The child readily mixes fantasy and fact. This flexibility may account for the richness of clinical material that may be obtained through symbolic play techniques with children. At this stage they literally act out their inner fantasies through the use of dolls and the like, losing themselves in the context of play so that it is no longer "play" in the adult sense of the word, ft is only gradually that the child separates the two domains of internal and external reality. This final separation begins to be accomplished when the child is able to form true concepts and has completely mastered verbal means of expression.

Between the phantasmic level of inner experience and the eventual mature form of psychic reality, Arieti postulated the emergence of a mental construct that he calls the "endocept." By this concept Arieti means a primitive organization of memories and images that, however, are nonrepresentational. The endocept is a feeling state that cannot be expressed with the precision of language: it is "at times experienced as an 'atmosphere,' an intention, a holistic experience which cannot be divided into parts or

words . . ." (p. 97), comparable to what Freud has described as the "oceanic feeling." This experiential level can be relieved in adult life in aesthetic experiences or in certain empathic feelings toward others.

However, in regard to purely cognitive growth the phantasmic world of paleosymbols is replaced by a primitive attempt at logical thinking. Arieti calls this stage of experience "the paleological world," stressing both its primitive and its logical characteristics. During the first stage there is an attempt to structure experiences and to associate events into broader categories, but the associative linkages are highly arbitrary and idiosyncratic. Arieti describes this clustering of mental events as a "primary aggregate," appearing like a strange agglomeration of disparate things put together, as they are in a collage. At other times it may be recognized as an embryonic structure from which conceptual structures eventually emerge. Or in some cases it may even embrace a field that at higher levels of development corresponds to a highly abstract concept. The primary aggregate form of cognition is replaced by "paleologic thinking." While not as yet conforming to the adult standard of Aristotelian logic, this form of mentation is not haphazard; it does follow specific laws or organization in which elements of thought are arranged into classes. However, the characteristics by which this organization of elements takes place appear insignificant or unessential to the adult. Objects or events are seen as identical if they have one quality in common. This stage is comparable to Piaget's preoperational level, where

objects were associated by their most prominent perceptual quality, as well as to Werner's *pars pro toto* functioning. It is also similar to what Freud had described as primary process thinking as universally manifested in dreams. For example, an individual may dream that he is in the presence of a king, and on analysis of the dream he will reveal that the king was representative of the dreamer's father. Here a similar element (exalted authority) had been used to create a paleologic identification. In view of the similarity of paleologic thinking to the primary process, Arieti terms its form of cognitive organization the "primary class." In contrast, what Arieti calls the "secondary class" (similar to Freud's secondary process) is a collection of objects or events that have elements in common, but these elements are seen as similarly modifying the event or object. Each of these similarities is seen as separate from the object that may be abstracted or conceived of in pure form. This type of organization that underlies adult thought does not deduce identity from similarity. However, in pathological states such as schizophrenia, there may occur a reversal to primary class formation, explaining the peculiarities of thought found in this disorder. This "teleological regression" to primitive forms of cognition is utilized to satisfy inner needs that cannot be gratified in reality.

While the phantasmic world was predominantly visual and static, the paleologic world is mainly auditory and utilizes language. Together with linguistic forms there is also an appreciation of sequence and causality. The

paleologic world is not inhabited by copied images of reality, but by rudimentary abstractions. The child can begin to reason and to build on his experience: he can separate similar data from the manifold of objects and begin to organize these objects into classes. However, because this process of abstraction is far from complete, the part is often confused with the whole, or two dissimilar events can be conceived of as identical. In other words, reality can be severely misunderstood and as a result internally misrepresented. As a result children are prone to make generalizations that follow a primary class organization and are unfortunately retained into adult life. These early misrepresentations are all too often seen in the irrational behavior of adults.

Concomitant with this increased ability to organize life events, the child begins to consider problems of causality. Prior to this stage, according to Arieti, the child's world is acausal, events simply occur. As the child begins to give causes to events, however, he utilizes extremely teleological explanations in which most things occur because someone has so willed them. Arieti speculates that this explanatory model is chosen by the child because so much of his life is actually determined by the will of powerful adults. The pertinent aspect of this new dimension of thought for the emotional and cognitive development of the child is that events are caused by people and thus one is responsible for these events. This new insight is necessary for what Arieti calls "third order" emotions. These emotional states presuppose a knowledge that a person can have an emotional affect on another, that one

can cause a feeling state in someone else. Typical of this highest class of emotions are depression, hate, love, and joy. Here again Arieti is stressing that affective states grow in correspondence to cognitive development.

When the child reaches the level of conceptual thought—that is, his internal world consists predominantly of consensually validated concepts, rather purely personal symbols or images—secondary process mechanisms truly prevail and concepts are organized into secondary classes. This type of cognition becomes perfected through childhood and reaches true prominence in adolescence. Arieti's use of the term "concept," however, encompasses more than is generally acknowledged by developmental psychologists. He is more interested in internal concepts such as one's self-image or one's view of the mothering figure. These concepts are in a state of change throughout development just as concepts of geometry or logic differ at various stages of childhood. Furthermore, according to Arieti, these concepts should be viewed as cognitive structures in their own right. Arieti believes that ultimately we are motivated and gratified through mental concepts rather than through instinctual energies. As the child develops, higher order concepts form his aspirations and fears. These mental structures should be seen as cognitive and not reduced to physiological drives. Here there is a blending and reinforcing of the affective and cognitive aspects of development. Even neurotic defenses should be viewed as cognitive configurations rather than solely emphasizing their affective or energetic basis. To quote one of Arieti's

recent articles:

> In a large part of psychiatric, psychoanalytic and psychological literature, concepts are considered static, purely intellectual entities separate from human emotions and unimportant in psychodynamic studies. I cannot adhere to this point of view. Concepts and organized clusters of concepts become depositories of emotions and originators of new emotions. . . . Not only does every concept have an emotional counterpart, but concepts are necessary for high emotions. In the course of reaching adulthood, emotional and conceptual processes become more and more intimately interconnected. It is impossible to separate the two. They form a circular process. The emotional accompaniment of a cognitive process becomes the propelling drive not only toward action but also toward further cognitive processes, [p. 23]

At each stage of development the evolution of cognitive structures that allow for a greater behavioral repertoire with the environment also creates a more sophisticated internal world with the emergence of higher level emotions and more abstract methods of mentation. Thus the motivation of the individual varies according to levels of development. Greater cognitive abilities give rise to higher order emotions, which, in turn, push toward growth of awareness, interpersonal relationships, and abstract processes.

In summary, Arieti has attempted to explore the growth of "inner reality" and the interlocking relationship of affective and cognitive structures in development. Furthermore, he has suggested that some psychic structures that are pertinent in everyday behavior, such as the self-concept, be viewed as cognitive entities that grow through ontogenesis. Arieti has stressed that the emotional aspect of development should not be neglected, and the

reconstruction and understanding of the inner world of childhood has an important place in the study of cognitive development.

Conclusion

From the foregoing presentation of current theorists, it becomes apparent that the developmental process is directed at self-regulatory behavior and the relative independence of behavior from immediate stimulation. Following a period of primarily reflexive, innate behavior, most theorists describe a stage of internalization of the environment so that events in the world can be mentally represented. Once this internal world is created, the child begins to structure stimuli and select adaptive responses rather than reacting automatically. However, as has been shown, this early representation of the environment is impressionistic and prone to error. The child is still bound to an egocentric yet concrete view of his environment, in which events and objects are associated by primitive logical linkages, into "nestings" or "primary aggregates" rather than hierarchical and logical classes. When the child begins rationally to order experience, it appears to be on a perceptual rather than logical basis. He responds to what is most striking in his environment rather than through understanding.

The last step in cognitive development, that of reason over appearance, is what Piaget has termed operational thinking. This divorce of thought from

appearance is perhaps the true hallmark of the human psyche and the very foundation of human functioning. The reliance on logic and the attempt to formulate cognitive laws to order the chaotic world of the senses are the ultimate goals of cognitive development. It is equally important, however, to realize that cognitive development does not occur in a vacuum, but is interwoven with the development of internal emotional life as well as increased sensory and motor capabilities.

For many years the study of the ontogenesis of thought was predominantly an academic, ivory tower preoccupation. Today, however, the complexity of our modern industrial society, greater than at any time in the history of civilization, requires of each individual cognitive abilities that in the past were the province of a very small privileged minority. Despite this requirement for more sophisticated levels of mentation for both economic and social survival, an inordinately large percentage of individuals do not achieve this ultimate aim and cannot share in the rewards or responsibilities of modern society. The study of how the mind develops, the forces that affect this development, and the ways to correct deficiencies due to both internal and external forces has thus become a desperately important scientific discipline, not simply for the satisfaction of intellectual curiosity, but for the greater benefit of all.

Notes

[1] An actual incident may demonstrate the role of cognition in the behavior of children. A three-year-old girl whose father often traveled by airplane developed an enthusiasm for flying. When the family planned to take a vacation and to travel by air the girl was ecstatic. However, when they were ready to board the plane the young girl panicked and refused to go on the plane. After calming her down, her parents inquired about the reasons for her "plane phobia"; the girl quite simply and honestly replied that she didn't want to get on the plane because she didn't want to shrink. The girl had been watching planes taking off and diminish in size as they became airborne, and her immature concept of size constancy did not allow for such rapid and extreme changes. The point is that her fear was a result of her immature cognitive ability and not of underlying dynamic events or prior learned habits.

[2] Hebb developed neurophysiological correlates of these types of learning. Very briefly, early simple percepts create "cell assemblies" or self-stimulating reverberating neuronal circuits in the brain. More complex impressions are stored in the form of "phase sequences" made up of a series of cell assemblies in a specific series. Although this aspect of this theory is important in neurophysiologv, its detailed explanation in terms of anatomy is beyond the scope of this chapter.

[3] In neurophysiological studies Hernandez-Peon, *et al.,* have found that distraction tends to shut out information. Similarly Galambos, *et al.,* have shown that stimuli that are not reinforced in terms of reward or punishment are extinguished and not recorded by the brain. The

analogy is that unless language or sounds have meaning for the child they will not be integrated.

[4] See Chapter 49 American Handbook of Psychiatry Volume 1 for an exposition of these aspects of Werner's theories.

[5] These concepts clearly have their roots in biological theory. For example, primitive embryonic cells are undifferentiated and similar. Through maturation these cells differentiate and become capable of performing specific functions of the various organ systems. Furthermore, the cellular structure ultimately forms a hierarchy so that certain cells control the activities of others and direct the organisms' behavior. These two principles, differentiation and hierarchization of parts, form the essence of Werner's definition of development.

[6] In a rigorous manner Piaget has been able to characterize formal operations as a system of four cognitive processes: i, identical transformations; n, inverse transformations; r, reciprocal transformations; and c, correlative transformations—each describing a process. Significant as this reduction is, a thorough exposition of it is beyond the scope of this summary.

Chapter 16

Early Language Development

Katrina de Hirsch

Introduction

Freud said that language brings into being a higher psychical organization. This chapter discusses some aspects of language acquisition, a process that is part and parcel of the young child's organismic growth.

The linguistic development of the child, according to Lewis, is determined by the interaction of many factors: those that spring from within himself, those that derive from the interplay between him and his mother, and those that impinge upon him from the particular culture to which he belongs.

Consequently there are several ways of looking at language acquisition, each concerned with different aspects of verbal development.

The potential for language is laid down in the central nervous system.

Thus one focus of interest is upon the biological and neuro- physiological factors that make possible the development of language and its specific human characteristics: the ability to symbolize.

Another focus of interest is concerned with the affective aspect of communication, which develops in the matrix of the mother-child relationship. The role of language in the formation of the ego is related to this inquiry. It is by no means clear, according to Edelheit, to what extent ego organization is reflected in the language system and to what extent the internalized language system constitutes the regulatory function of the ego.

An equally legitimate concern is the sociocultural determinants of language. As a result of the growing awareness of deprived children's linguistic and learning difficulties, which are closely related, this aspect is, at present, very much in the foreground.

A relatively new type of investigation is being undertaken by those linguists who investigate the developmental facets of the phonemic, semantic, and syntactical elements of the child's language.

It is far beyond the scope of this presentation to sketch more than the outlines of the different stages in language learning.

Stages of Language Development

Earliest Responses to Auditory Stimuli and Vocalizations

There is some evidence of fetal response to sounds.'' According to Eisenberg, the cochlea seems to be functional at about the twentieth week of intrauterine life, and the basic mechanism for coding intensity and frequency is probably operant by the thirtieth week of gestation. The neuronal mechanisms for processing sounds are fully mature at birth. Toriyama, *et al.,* reported EEG responses to 60 db tones bursts three hours after delivery. Recent data sharply contradict previous views of the newborn as presenting an auditory *tabula rasa.* Eisenberg's laboratory studies involving several hundred infants demonstrate that neonates not only respond to auditory stimuli but also respond selectively. Pure tones are far less effective in eliciting responses than are complex ones.

The function of the birth cry is physiological, serving to establish normal respiration and oxygenation of the blood. Palmer maintains that the cries of infants damaged prenatally or at birth differ in pitch, rhythm, and volume from those of normal babies. Karelitz and Fischelli have found that certain crying contours may be predictive of mental retardation.

From his earliest days the baby vocalizes, utilizing the expiratory phase of the respiratory cycle. The air flow is modified by the vocal cords and the various parts of the peripheral speech mechanism, setting up sound waves that may be detected auditorily. The identical process holds for all vocal

productions: the baby's cry, his cooing, and at a later time his speech. Liebermair' has shown that the wave forms of the baby's cry have the same characteristics as adult sentences. Long before the child uses words, alterations in breathing produce variations in intonation that are, in turn, instrumental in carrying messages.

Hunger, pain, and discomfort will make the neonate cry. These discomfort cries approximate low front vowels and are usually nasalized. Shortly afterward the active and alert baby will produce different kinds of vocalizations after feeding and during states of wellbeing. Such sounds consist of low front vowels combined with high back ones and a few consonants such as guttural /r/ and palatal /g/. Very early, then, the child uses the physiological mechanisms of respiration and phonation for expressive purposes, and for the mother each characteristic vocal pattern has a distinct meaning.

Quite early the baby distinguishes between male and female voices and between friendly and angry voices. By measuring changes in heart rate McCaffrey and Moffit demonstrated in two different laboratory studies that 11 to 20 eight-week-old infants distinguish between phonemic contrasts of both synthetic speech and the human voice. On the basis of their experiments Elmas, *et al.,* concluded that perception in the linguistic mode may well be part of the biological makeup of the organism and must be operative at a

surprisingly early age. That babies do a far greater amount of discriminative listening than has hitherto been shown is demonstrated by Friedlander's work. The infant's experience with hearing spoken language, he believes, is an indispensable requisite for his eventual ability to speak it.

Long before children respond to the phonetic patterns of words, they respond to the prosodic features of language, to the variation in intonation and pitch that carry the emotional load of communication. The mother's vocalizations are at first experienced as part of the total constellation that includes her smiling face, the presence of caresses, and the satisfaction of bodily needs. Turnure has shown that a three-month-old baby can be "tuned in" to a tape recording of his mother's voice, even in her absence.

Cooing

Before they are three months old babies engage in playful cooing interchanges with the mother when she imitates the baby's own sounds. This is probably a universal phenomenon. Piaget observed such early forms of interaction from the first month on and called it "verbal contagion." These vocalizations show a preponderance of back rounded vowels and—at a somewhat later stage—glottal stops, in addition to clicks of several varieties. In the fourth month, with increasing chewing activities as the result of the introduction of solid foods and the baby's tendency to put all sorts of objects

into his mouth, lip and tongue muscles become more active and the cooing interchanges become more varied and livelier.

Mother-Child Dialogue

The vocalizations that mothers use with their babies are tailored to the child's affective needs. They differ from those she uses in other situations in a number of features: in dynamic accent, in melody and rate, and in a marked tendency to rhythmic iterations. Snow says that children who are learning language have available a sample of speech that is simpler, more redundant, and less confusing than adult speech.

Di Carlo has made the pertinent observation that the mother caresses the child with her voice. Wyatt calls the dialogue between the mother and her baby a process of mutual feedback. The learning of the "mother language," she says, is achieved through unconscious identification. Infants are continually talked to in situations that are essential to their well-being. The vocal and affect communication between mother and child during bathing, feeding, and dressing must of necessity play an important part in the child's communicative attitudes, of which language is but one aspect. The mother's voice is undoubtedly heavily cathected for the baby. The extent to which this phenomenon bears on subsequent listening attitudes has not been explored, but it is quite possible, as maintained by Eveloff, that the first 18 months are

crucial for symbolic language development and that serious flaws in the interaction between the baby and the mothering adult would have repercussions in terms of the child's linguistic and cognitive development.

We do know that normal maturational processes are delayed or disturbed in children brought up in institutions. This is convincingly shown in Provence and Lipton's study of such infants, whose vocal and verbal development is often severely delayed. We have no systematic investigations comparing the early vocalizations of institutionalized infants with those of well-mothered babies, who have a repertoire of most of the vowels and half of the consonants by the end of the first year. Not all institutions are alike, of course. Tizard, *et al,* found that the language comprehension scores of young children correlated significantly with both the quality of the speech directed to them and the way the residential nurseries were organized. A careful comparison of the vocalizations of infants even in "good" institutions with those of babies who have received ample sensory and affect stimulation might, nevertheless, reveal much earlier deficits in institutionalized babies than those shown by Brodbeek and Irwin, who found that differences in verbal development between deprived youngsters and middle-class ones begin to show at 18 months. It is of interest that in a later study Irwin proved that with very systematic stimulation beginning at 14 months, the phoneme frequency of stimulated babies was significantly higher than that of their control group.

Babbling

Between the fifth and the tenth month of life, usually around the time he attempts to turn over, to sit up, to drink from a bottle, the baby begins to babble.[1] There is no clear demarcation from expressive sounds to babbling. The various stages of language development overlap. From short cooing phrases the baby proceeds to the use of long strings of sounds that are no longer tied to specific situations. Now the baby lies in his crib, amuses himself with his fingers and toes, and plays with sounds that he produces spontaneously, obviously for the sheer pleasure of making them. These vocalizations are presymbolic. They are playful and probably autoerotic. There is no mistaking the intense gratification the baby derives from the mouthing of sounds and the enjoyment he gets from this repetitive playful experimentation and stimulation. It is thus not surprising that analysts are impressed by the role this particular oral activity plays in early psychosexual development.

During babbling the baby "discovers" how to mold the outgoing breath stream so as to produce a whole repertoire of sounds. At the same time an auditory feedback loop is being established. As sound-producing movements are being repeated over and over again, a strong link is being forged between tactual and kinesthetic impressions, on the one hand, and auditory sensations, on the other. A pattern of alternate hearing and uttering is set up.

Sounds—and as time goes on they take on a more and more repetitive character—are no longer random but tend to resemble the phonetic and intonational configurations of the original utterance. One of the main functions of babbling, therefore, is an intensive kinesthetic-proprioceptive auditory learning experience, resulting in primitive sound- movement schemata. The baby not only produces a whole range of different sounds but also derives pleasure from those he himself produces. The self-stimulation the baby engages in during this activity may play an important role in his increasing awareness of linguistic organization.

Every mother knows that she can stimulate long babbling conversations between herself and her child. It has been shown that nonsocial stimuli such as the sound of chimes do not increase vocalizations. Nor does the mere presence of the human being result in more copious babbling. It is the human voice that stimulates babbling, and babbling is reinforced by the presence of a significant adult. Mother and child engage in what Piaget calls "mutual imitation." The baby, stimulated by his mother's vocalizations, produces more of his own. Thus, even at this early stage, a corrective feedback mechanism is established that, according to Wyatt, is a *sine qua non* for smooth language development. Of course this is possible only if the child has learned to store— if only for a limited time—and to retrieve the auditory-motor configurations the mother models for him. It is she who monitors the baby's vocalizations by providing the phonemes used in her own linguistic culture.

Normal children vary in the amount of babbling they do; some babble early, some much later. However, intactness of the central nervous system is a prerequisite for the auditory-motor feedback loop that stimulates babbling behavior. This loop does not become functional in babies who are deaf or hard of hearing. Deaf babies babble, but they discontinue doing so after a while because they lack the stimulation derived from hearing their own sounds as well as those of the environment. New investigations have demonstrated that with amplification at the babbling stage, that is to say, with the very early establishment of the auditory feedback loop, the language development of severely hard of hearing children approximates that of normal ones.

It has been assumed that babies from widely differing language backgrounds have an extensive repertoire of babbled sounds that include not only those of their mother language but also many others that drop out later Cruttenden, in an interesting analysis of the babbling of his twin girls-—admittedly an atypical sample—maintains that this claim is not borne out by the facts. He did not, for instance, find fricatives or affricatives[2] /th/, /s/, /z/, /sh/, or /ch/ among his children's babbled sounds. He concluded that the range of babbled consonants is not nearly as extended as is often implied. Nevertheless, he believes that the babbling stage is important not only as a period for experimentation but as one in which the child's repertoire shifts in the direction of the language to be learned. Weir found that the sounds of five-

to seven-month-old Chinese babies differed from those of Russian and American ones. Early and selective imitation of input, therefore, must play a significant role in babbling. Quantity and quality of babbling varies from one child to the next, but as babies advance in age, their babbled sounds become more differentiated and more clearly patterned.

Echolalia

Around the tenth month, as control over volume and pitch develops, duplications become more frequent, intonational contours more distinct, and the baby begins to imitate the more patterned utterances he hears in his environment. He starts repeating words heard, but not necessarily understood. It is the main accented word in a sentence, the word that is most heavily loaded with affect, that is selected for imitation, and it is the initial syllable of such a word that is usually chosen for duplication.

Echolalia is a normal phase in language development, and echolalic responses comprise a significant portion of children's speech up to 27 months. Toddlers often repeat words or combinations of words for purposes of clarification, to try them on for size as it were. Echolalia is pathognomonic for mental retardation, autism, or aphasia only if it is the only response available to the child, if it has an intensely compulsive quality, or if it occurs in older children.

Listening and Language Comprehension

That effective listening is indispensable for the development of speech and language has been known for some time. Infants' systems for processing acoustic and linguistic input mature much faster than those for generating language. How do babies make some order out of the "buzzing confusion" that surrounds them? Friedlander says they face a monumental task learning to order auditory and linguistic signals into more or less stable categories. In a series of highly ingenious experiments, he has shown that, among other achievements, eight- to fifteen-month-old infants can discriminate between backward and forward speech and between flat and bright intonations.[3]

Long before they decode linguistic patterns, children learn to detect certain regularities from the intonational contours and phoneme boundaries of the speech that surrounds them. An enormous amount of learning, therefore, must be going on during the seemingly passive listening done by very small children. This fact has important implications for early intervention and enrichment programs.

Crude processing of input precedes language comprehension. We assume that by a process of selecting, filtering, and transforming acoustic input, small children arrive at the decoding of linguistic information. What are the requisites for comprehension? A fundamental requirement is that the child be able to make a modicum of sense out of the world that surrounds

him, that he use some objects appropriately, and that he has a rudimentary sense of self, of being separate. Lewis- says that the child responds first to the intonational configurations that form part of specific situations. Slowly the phonemic pattern becomes intertwined with situational and intonational features, until very gradually, as further differentiation takes place, the phonemic pattern becomes dominant, irrespective of the situation. Around the age of 12 months the child shows signs of understanding simple phrases and commands, particularly those that are heavily loaded affectively.

Expressive Language

Although new research has thrown light on some of the factors that determine the ability to process verbal information, we do not really know what happens when the child *produces* his first meaningful utterances. Indeed, there is little agreement on what constitutes the first word. Is it the word the child uses in contexts other than imitation, the utterance that stands for an object, a person, an event? McCarthy argues that there is a tremendous gap between the mere production of a word and the symbolic representational use of that word in an appropriate situation.

In recent years a lively controversy has arisen between the proponents of learning theory and nativistically oriented researchers regarding the emergence of the first meaningful words. Learning theorists argue that

language is slowly shaped out of the multitude of babbling sounds by means of selective reinforcement on the part of the parents, who show their delight when the child produces sound combinations that resemble actual words. As a result of such reinforcement, the child gradually begins to associate such sound combinations with specific situations, people, or objects. Linguists such as Jakobson and Halle, on the other hand, draw a sharp dividing line between babbling and representational speech. Brown, in an intermediate position, suggests a "babbling drift" in describing the transition from babbling to language.

We know that at the age of 12 months the child is able to imitate the intonational contours of his mother's speech. Many preverbal babies utter long strings of sounds that resemble those of adults in melody and pitch. Mothers respond to these vocalizations as if they were definite messages, statements, commands, or questions. A message is clearly associated with the modulated strings of sounds the baby produces even before he can utter a single word. Advanced babbling *is* a sort of language, and we cannot, therefore, talk of the emergence of symbolic speech as a sudden event, but must look upon this development as an ongoing process that goes through a series of interrelated and overlapping phases, each new phase representing not merely an addition but a new and more highly integrated configuration.

Linguistic Dimensions

Several dimensions of language are described by linguists: (1) the phonological refers to elementary verbal forms and their combinations into words; (2) the semantic deals with word meanings; (3) the syntactical concerns the formal relations and underlying rules for processing and generating sentences. Developmental linguists attempt to construct a model to explain the child's unfolding ability to understand and produce an infinite number of sentences.[4]

Phonology describes the matrix of features that differentiates one speech sound from another by virtue of certain characteristics. It deals with contrasts between certain features, such as the one between voiced and voiceless sounds, for example, /p/ and /b/.

For the infant sounds are probably at first indistinguishable from one another. As children's perceptive faculties develop, they gradually learn to differentiate between coarser and finer shades of sounds. Research on the perceptual distinctions children are able to make between birth and the age of three years is relatively recent. Jakobson postulated that successive perceptual contrasts are acquired in a more or less consistent sequence. One of the first is probably the distinction between vowels and consonants.[5]

There are considerable variations between children when it comes to production of sounds. Some, for example, acquire fricatives far earlier than

others. Not only the timing but also the quality of sound reproduction varies. Many children have trouble not only with a single phonetic feature but with several of them. A child who substitutes "dar" for "car" misses not only the place of articulation— alveolar rather than velar—but also the voiced-nonvoiced contrast. Menyuk found that Japanese children acquire mastery of the phonological system roughly at the same time and in the same order as do American youngsters. This suggests that the hierarchy of sound acquisition depends on the developing productive capacity of the child.

Not all of the 40-odd sounds of English are mastered simultaneously. The child's earliest utterances contain only two or three phonemes. At 18 months he may cope with from eight to twelve of them, including diphthongs. From then on his production of the sounds of his language increases by leaps and bounds as a result of further differentiation. Sudden spurts are followed by phases of consolidation. American children manage 80 per cent of all sounds by age five.

As a rule children use only those sound sequences that are part of their native language. An English child will not, for instance, produce the cluster "pf," which is a common one in German (as in the word "pferd"), but he will use the cluster "pl" which is acceptable in English. Children do not usually need formal training to learn these rules. While it is obvious that the mastery of the phonological system of the language requires a degree of central

nervous system maturation, the child primarily needs a model. It is the mother who usually serves as the primary language model and who literally feeds back to the child those sound sequences that are acceptable in his language environment. During certain critical stages of language learning, the model is of decisive importance in the mastery of the phonological system of the language.

The affective and communicative exchange between mother and child also plays an important part in the acquisition of vocabulary and in the growth of meaning, that is, in the *semantic* dimension of language.

Most children begin to use symbolic utterances between 12 and 20 months. They usually select those words that provide essential information or those that are strongly affectively colored. Words at this age reflect the magical universe of the small child. There is a close link between the name and the qualities of an object. Single words at this age may also stand for groups of experiences and configurations that are lumped together (holophrases). Many children cling to one-word sentences for a long period, using intonation to express a variety of meanings. The upward shift in pitch might indicate a question, for example, car?

Brown says that parents intuitively provide the names that reflect the structure of the child's world. The parents may say, "spoon" and not

"silverware," using the more concrete referent in preference to the more abstract one. But they will say "fish" rather than "trout," using the general rather than the more specific referent. Children enlarge their vocabulary through a process of extension and restriction. Its growth is characterized by continuing modification of meaning, involving both the acquisition of new words and the expansion and refinement of word meanings previously learned. Increasing differentiation is reflected in more precise usage. "Doggie" is at first only the child's small, fluffy toy dog; a little later the word describes the real dog the child sees at a neighbor's, and finally it stands for all members of the species "dog." The meaning of the word has been expanded. The opposite process takes place when the child says, for instance, "He write a picture." When he learns that the word "write" refers only to those graphic activities that involve letters and numbers, he has restricted and refined the meaning of the word.

Some concepts and the words that represent them are learned earlier than others. Only 10 per cent of 240 two year olds in Palmer's group' understood the word "around." Concepts such as "backward" are difficult for three year olds."

The development of meaning, which belongs to the semantic aspect of language, cannot be explained by associative bonds. Meanings are not constant. They change throughout the individual's entire life. At age three the

child uses 700 to 800 words, and between three and five years he adds at least 50 new words to his vocabulary each month. The growth of meaning depends on the verbal richness of the child's cultural background and probably on his linguistic endowment (although linguists do not agree, clinicians who work with language-delayed children know that this endowment may differ within social milieus and even within given families). This growth depends primarily on the mother's interest in and knowledge of words, on her ability to clarify shades of meaning, on the easy give and take between her and her child, and on the constant feedback provided by the significant people in his environment. Stodolsky's study indicated that the best single predictor of Negro children's recognition vocabulary was the mother's vocabulary score on the Wechsler Intelligence Scale for Adults. The maternal teaching variable was the extent to which the mother defined tasks and named specific qualities of the environment. Thus the child's cultural and affective milieu play a vital part in fostering delight in the use of words and interest in shades of meanings. Children do need models, above all, for the acquisition of the lexical aspects of communication.

On the other hand, modern linguistic theory postulates that in the development of *syntax*, the set of rules that governs the organization of the more or less limitless number of possible utterances, imitation is not of primary significance. Children do need exposure in order to be able to deduce the underlying rules of language, and linguists admit that the very young child

begins with repetition of bits of speech heard. Because of limitations in their auditory memory and because they cannot as yet program longer units, they repeat only two to four items. These repetitions are usually systematic reductions of the input perceived and are apparently processed as units rather than as lists of single words. (Children repeat those parts of speech that carry the significant information.)

Learning to generate complete sentences (as opposed to repeating) is a slow process and proceeds from primitive to more and more differentiated syntactical and morphological structures. Before or around their second birthday, children produce their first spontaneous, nonimitative two-word combinations. Brown points out that the two single utterances "push" and "car" are not simply joined. The unit is programmed as a whole, and "push" is subordinated to "car" by means of lesser stress and lower pitch. The transition from the generating of single words to two- word units that are hierarchically organized is a tremendous step forward. Words can no longer be changed around like beads. The position of words in the string becomes relevant; the principle of word order, a powerful linguistic signal in English, is established.

Children's spontaneous two-word combinations, like their repetitions, consist of the most highly stressed and informative words— nouns, verbs, adjectives—content or "open class" words. This telegraphic speech is

characterized by the omission of functor words, prepositions, auxiliaries, inflections, articles. These constructions are slowly expanded by the use of modifiers such as "push pretty car" and are the building blocks of subsequent sentences.

Brown and Bellugi describe the next level, the noun phrase, as an essential milestone in the acquisition of syntax. In standard English a noun phrase consists of a noun and assorted modifiers: "my girl," "more coffee," and the like. Two or more such modifiers can be combined with nouns, and since children construct interim grammars on their way to linguistic mastery, they slowly learn the privileges and constraints belonging to each modifier. The noun phrase can be moved to different positions in the string and can even be replaced by a pronoun. According to Chomsky's theory, phrases are cohesive grammatical units. They reflect the child's discovery of basic phrase structure and lead to the formation of "kernel sentences," which are composed of at least two units: one functioning as subject, the other as predicate.

From such kernel sentences new forms evolve by additions, deletions, and rearrangements. Serialization is effected through the use of the word "and"; questions are formulated by prefacing sentences with "wh" words. Thus, beginning with the simplest two-word combinations, followed by noun phrases, one can trace the gradual emergence of elaborated structures.

Complexity and length of units increase simultaneously. By 36 months most children's linguistic development is so advanced that they are able to produce all of the varieties of simple English sentences consisting of up to ten or eleven words.[6] It is important to realize, however, that what children learn are not specific combinations of words but the rules that govern these combinations. Chomsky says that children internalize underlying grammatical rules on the basis of their exposure to limited numbers of correctly formed sentences. That language learning involves much more than the storing of longer and longer bits of utterances heard has been demonstrated by Berko. In a series of ingenious experiments she used nonsense words to test children's ability to apply morphological rules: that is to say, tenses, plurals, posses- sives, and so forth. The examiner points to a doll, for instance, and says: "this is a child who knows how to 'wug,' today he is . . If the child supplies "wugging" although he has never heard the present participle of "wug," he has spontaneously applied the underlying grammatical rule that asks for the ending "ing" in this particular construction. A child may have memorized the plural form "witches," Lenneberg says. But if he produces the plural "gutches," he shows that he has incorporated the rule that the plural of words ending with /ch/ is formed by adding /ez/. The very existence of "overgeneralizations" such as "mouses" (as in "houses") proves that the child has derived a set of abstract rules from the linguistic data to which he was exposed. These rules are basic to the decoding and encoding of

language.

Mastery of syntax is a gradual process. A three year old understands the contrast between subject and object in the active but not in the passive voice; this distinction belongs to a chronologically older age.

Controversies

McNeill and other nativists claim that children are born with a set of "linguistic universals" as part of their innate endowment and that they are neurologically so preprogrammed with a language acquisition device that they need only a minimum of stimulation for its realization. Language learning, they say, is reminiscent of embryonic development in the sense that it constitutes the unfolding of an inherent potential. A less radical position would be to postulate that children are born with certain propensities, "anlagen," that enable them to organize linguistic inputs into cohesive categories and structures. Goldstein referred to the organism's drive to "actualize" inborn capacities. As far back as 1907 the Sterns stressed that the child who learns to speak is neither a phonograph reproducing sounds nor a sovereign creator of concepts. His speech is the result of "convergence" of the continuous interaction of external impressions and internal systems.

Finally there is the behaviorist position, asserting that language learning depends on differential reinforcement on the part of adults who care for the

child.[7]

The universality and the consistency of normal language development would seem to speak for the nativistic position. Penfield and Roberts speak of a "biological timetable" for language development. However, while this holds for the majority of youngsters, there are, nevertheless, large variations in timing. It is the *sequencing* that is relatively stable. Most children pass through babbling, echolalic speech, two-word sentences, etc., on the road to fully developed verbal communication.

Stimulation

Lenneberg's position that normal language learning proceeds without actual training is correct only to a point. An enormous amount of informal teaching, or corrective feedback, goes on in most families. Mothers respond to their children's telegraphic speech by "expansion"; that is, they modify their children's utterances by adding functor words, auxiliaries, prepositions, etc., and in so doing, present them with a model of the nearest correctly formed sentence.[8]

This is not a form of correction. Cazden rightly points out that correction extinguishes communication. Expansion, according to Cazden, is most effective at "critical" stages of linguistic development when a growth in structure is taking place—an important fact to remember in terms of early

intervention. What expansion does is clarify and enrich verbalization at the very moment the child is engrossed in a situation that holds his attention. Young children focus attention best when they are affectively engaged. If a youngster cries out, "Teddy table hurt," and the mother takes him on her lap and says, "Poor Teddy, yes, you bumped into the corner of the table, it hurts," she is involved with him in a highly meaningful experience. Mothers filter their own output: they seem to know which stage in language development the child is passing through at a given moment. With young children they use the kind of constructions the children themselves will use a number of months later. In terms of content mothers deal very much with the "here" and "now." The timing and the tuning in to the child's concerns are all-important. There are mothers who fail to cue in. They do not expand their children's telegraphic utterances, and they thus miss an opportunity to enrich communication. Or they swamp the child with long and complex verbalizations that, in his terms, are totally irrelevant. Wyatt presents some excellent examples of the kind of affective and linguistic interaction that fosters comprehension and use of language and in the last instance presents the child with a view of the world.

Sociocultural Factors

Hess and Shipman look at the mother as a teacher, a programmer of experience in the preschool years. They discuss different styles in information

processing, which is mediated through language. Nobody who is familiar with language stimulation programs involving young children and their mothers will deny that there are large differences within the same social group in the way mothers foster linguistic and conceptual development. Thus it is not social class alone that determines the child's exposure to adequate language models. Nevertheless, the experiments carried out by Hess and his group convinced them that the teaching style of many lower-class mothers is less explicit and therefore less effective than that of middle-class ones. Tulkin, *et al.,* found that working-class mothers often did not believe that their children were able to communicate and hence felt it was futile to attempt to interact with them verbally. The fact that these mothers' handling of their children, in general, tends to be more authoritarian and less based on verbal exchange than that of middle-class mothers would account for some of the intergroup differences.

It was Bernstein who originally postulated that the very speech of lower-class individuals is characterized by rigidity of syntax and limited options for sentence organization. Lower-class speech, Bernstein said, is less elaborated and more restricted than middle-class speech, and it offers less opportunity for categorizing environmental stimuli. As a result it is relatively ineffective for conceptualization.

Bernstein's work, which is both interesting and controversial, has been

under heavy attack by sociolinguists. They maintain that black dialect is by no means a more primitive language than standard English, but is rather a *different* language. Baratz, Stewart, Taylor, and others have demonstrated that lower-class black children show the same proportion of grammatical transformations as do middle-class children of comparable age.

Black youngsters incorporate the linguistic rules of *their* language environment. The use of the double negative, for instance, is an accepted feature in adult black speech and cannot, therefore, be considered to be defective in the black child. A recent paper by Quay shows that much of the research discussing language deficits in black children is based on language expression rather than on comprehension, which clearly puts youngsters who speak a dialect at a disadvantage. Comprehension is a much more sensitive indicator of a child's linguistic maturity than is production.

Moreover, it is not legitimate on methodological grounds to evaluate the language of one subculture by means of norms derived from a different subculture. And it is not justifiable to use developmental language scales standardized on middle-class children as criteria for youngsters who do not speak standard English.

Cazden, who has dealt extensively with the deficit-difference issue, feels that both concepts are inappropriate. For one thing they are probably too

global. Middle-class children's vocabularies are richer and more differentiated than those of lower-class black youngsters, but the grammatical competence of lower-class black children is probably comparable to that of their middle-class peers.

What counts in the last analysis is children's communicative effectiveness. Thus Cazden stresses the speaking situation and the children's ability to perceive and categorize a social situation and to adjust their speech to its requirements.

The literature is replete with statements referring to the superiority of girls' early language development. McCarthy' says: "Whenever groups of boys and girls are well matched in intelligence and socio-economic background . . . there appear slight differences in favor of girls." Not only length of sentences, but almost all other measures that show developmental trends with age—articulation, word usage, complexity of output, and grammatical competence—demonstrate slightly more rapid maturation in girls. Kagan's report that, in contrast to boys, vocalizations of girls between four and fourteen months showed greater stability, independent of social class, is of interest in this context. Scores on an early vocalization index proved to be a far better predictor of subsequent cognitive development in girls than was the case with boys. One might speculate that the earlier neurophysiological maturation of girls as compared to boys is an important factor in the linguistic superiority of

girls, at least during the earlier years.

Birth Order

Another striking fact is the marked linguistic superiority of only children. McCarthy points out that this superiority is out of proportion to that which could be expected from their sex, mentality, and socioeconomic background, and she relates it to only children's far greater opportunity for linguistic and affect interaction with adults. Firstborns do better than younger children probably for the same reason. Twins and triplets, who have to share their mother's lap, are worse off then single babies. The study of the language development of identical twins is complicated by the fact that it involves not only neurophysiological factors (many twins are prematurely born) but also problems of identity. The tendency of twins to create a universe separate from the world that surrounds them may be another variable.

Language and the Organization of the Child's World

It is impossible to overrate the importance of language in children's development. In the young child speech is a means of expressing feelings and demands, a thing to play with, a device that substitutes for action, or an attempt to control the behavior of others. Kaplan describes young children's speech as governed by affective needs, including play, and as such infused

with highly personal meanings.[9]

The world in which we live is conceptually organized, and language makes this organization possible. Language is our main tool in the construction of a comprehensible universe. The preverbal child probably has some schemata, some ways of ordering the world, but these schemata can be assumed to be amorphous. The ability to use verbal symbols permits the child to impose order on his experience and to arrive at some clarification of his outer and inner cosmos.

Language, Edelheit states, is an obligatory component of human biological organization and plays a crucial role in the formation of the ego, which is the special human organ for adaptation. Ego development depends largely on an optimal level of verbal expression, and conversely ego defects of whatever origin are reflected in disturbances of language. As far back as 1936, Anna Freud wrote: "The association of affects and drive processes with verbal signs is the first and most important step in the direction of mastery of instinctual drives. . . . The attempt to take hold of the drive processes by linking them with verbal signs which can be dealt with in consciousness is one of the most general, earliest and most necessary accomplishments of the ego, not as one of its activities."

The secondary process requires word representation. Ability to

verbalize helps to delay action; it constitutes the "trial action" Freud speaks of. Words are needed for purposes of impulse control. Postponing gratification is infinitely more difficult without the use of verbalization.

With the acquisition of language the distinction between self and nonself becomes clearer. The child probably has an emerging sense of self even before he begins to use words. But the distinction between self and nonself becomes much more differentiated when categories such as "I" and "mine" emerge. The two later stages of the separation-individuation phase™ run parallel with the most rapid spurt in language development. One would assume that there is a reciprocal relationship between these events, one fostering the other. According to Despert, "Since the appearance of the first person pronoun in language development follows that stage of individuation which corresponds to the child's consciousness as one, whole and apart from others, the importance of this sign cannot be overestimated."

Things acquire stability and permanence by being named. Names help to anchor the significant people in the child's environment; they reassure him that the mother will return even if she is gone for a while; and they thus contribute to what is called object constancy.

Language permits the child to externalize magical and omnipotent fantasies and thus renders them less dangerous. It makes possible the

distinction between fantasies, on the one hand, and reality, on the other. The shift from a magical, prelogical world to a reality- oriented world is mainly accomplished by language. The labeling of inner states helps the distinction between the outer and inner cosmos, thereby assisting reality testing, one of the most essential functions of the ego.

The formation of conscience is immensely facilitated when the child learns to internalize rules and laws. Such internalization remains precarious without the use of verbal concepts.

Learning to express verbally feelings of fear, pain, and sadness protects the child from being overwhelmed.

It is well known and fully accepted that language is an indispensable tool for cognition. There is thus no need for extensive elaboration of this point in the present chapter although it might be helpful to stress a few points. Luria showed that language stabilizes perception and mediates also during nonverbal tasks. Kimbal and Dale have shown that forming categories of color names facilitates recognition. By freeing the child from the here and now, by making possible operations such as classifying, serializing, and formulating, words allow the child to discover the common properties of perceptions and events and permit him to group single entities into larger wholes. Language helps in the shift from associative to cognitive levels of learning and paves the

way for high order operations.

To quote a poem by O. Mandelstam cited by Vygotsky: "I have forgotten the word I intended to say and my thought unembodied returns to the realm of shadows."

Notes

[1] Cruttenden objects to the definition of babbling as the stage in which children utter sounds just for the pleasure of making them. He prefers a more objective definition and suggests that babbling be defined as the stage when the baby first produces "pulmonic-lingual" consonants, for example, dental and velar plosives, alveolar and palatal nasals, in addition to a growing variety of vowel-like sounds. The production of these sounds would imply "a new awareness" on the part of the child of how to combine tongue movements with breathing. This stage, he says, more or less ends with the emergence of the first words.

[2] In contrast, Leopold asserts that in the case he studied, affricatives occurred very early during cooing and babbling but quite late—in the last third of the second year—in imitation of real words.

[3] Friedlander's tape recordings of the children's "natural home language environment" and specifically of the language interaction between parents and children could provide important clues in terms of verbal competence at later ages.

[4] *Readings in Language Development*, edited by Lois Bloom, is an excellent introduction to developmental linguistics.

The author is aware of the limitations of the section that follows; it only attempts to summarize the groundbreaking work done in this area. Not only does the scope of the

chapter exclude a more penetrating summary, but also the original manuscript was submitted nearly two years ago and thus does not refer to much of the recent work. (The new book by Cazden, *Child Language and Education,* is an example.) The author realizes that her presentation is not only incomplete but also probably biased in favor of the transformational school of linguistics.

[5] Not discussed in this chapter is the "motor theory" of perception proposed by the Haskins group.

[6] Bloom feels that what is called "transformational grammar" describes only the most formal aspects of children's language development. Her own sophisticated formulations show that a child's identification and reproduction of a particular syntactical structure is intimately related to his interaction with the world of objects, events, and relationships.

[7] That the Skinnerian model of language acquisition is inappropriate has been shown in a brilliant review by Chomsky, who more or less demolished the theories expounded in *Verbal Behavior*. Nor can Braine's contingency and transfer of training theory account for even fairly elementary phrase structure. Although it is true that certain aspects of language learning in children are more dependent on contact with the adult than others (parent-child interaction has more impact on semantic and phonological than on syntactical development), it is far too simplistic to think of such learning in terms of even highly sophisticated stimulus-response theory. Children might learn words and even phrases by way of differential reinforcement on the part of the adult who "shapes" desirable verbal responses; they will not, however, acquire language—that is to say, the attitudes underlying communication, the investment in verbal exchange, and the joy of expressing subtle meaning by way of words.

[8] Brown makes the interesting differentiation between the adult's imitation of the child's speech by means of expansion and the child's imitation of adult speech by means of reduction.

[9] No attempt was made to discuss the development of inner speech, which appears more or less around the time when "egocentric" speech disappears. For a classic discussion of both, see Vygotsky, *Thought and Language.*

Chapter 17

The Juvenile and Preadolescent Periods of the Human Life Cycle

E. James Anthony

The Juvenile Period

Definition

The juvenile period, outside its legal sense, was a term incorporated by Sullivan into his developmental system, but others have classified the same chronological span of time in ways more reflective of their particular professional viewpoints. To the educator, for example, these are the years passed in grade school and bifurcated for good educational reasons into a primary triennium from grades one to three and an elementary triennium from grades four to six. For the developmental psychologist this is the era of middle childhood, a time of relative quiescence interposed between the turbulences of preschool and adolescence. This is the case both physically and psychologically. In the context of physical development there is a plateau

extending from the preschool to the pubertal growth spurts; Stone and Church have called this the "growth latency," suggesting that it may be a physiological counterpart of the Freudian sexual latency between the passing of the Oedipus complex and its reactivation in early adolescence. For the dentist the juvenile stage begins with the last of the baby teeth and ends with the complete eruption of the permanent set, minus the "wisdoms." In different theoretical systems of development, other prime characteristics have been accentuated. Piaget has pointed to the concrete operational mode of thinking, Sullivan to cooperation within interpersonal relationships, and Erikson to the opposing tendencies of industry and inferiority that can make or mar the school child. There would appear to be, therefore, some grounds for believing that the middle years of childhood represent a psychobiological moratorium in certain crucial and perhaps distracting areas that allows the child to restrict himself to the conflict-free spheres of ego "business" in order to learn as much as he can about the environment in which he lives and his own particular place in it. There is a growing flight from family life and especially from close parental contact, an increasing immersion in peer society, and a restless pursuit and exploration of a universe expanding in space and time with every year of development. The middle years form a self-contained world, irresponsible, irreflective, and halcyon, to which adults harken back with pleasure across the disturbing memories of adolescence. More recent investigations of latency have indicated that these golden

recollections are to a large extent a sustaining, utopian illusion and that the miseries of the middle years are as real and as scarifying as any experienced in other parts of the life cycle.

Descriptive Development

Physical growth during the middle years is surprisingly regular and free from breaks or spurts as long as the environment is optimal. The evidence for the existence of a midgrowth spurt between five and eight years is dubious; until more exact longitudinal data are available, there is every indication of a growth latency apart from minor seasonal variations that may be superimposed on the rate-of- growth curve. Growth continues at a slower pace: the average child entering latency at six years measures 3½ feet and weighs 40 pounds and the average child leaving latency at 12 years measures 5 feet and weighs 80 pounds. His muscular strength more or less doubles during the same period. Latency girls, in general, keep ahead of the boys and enter puberty earlier. Very little is known about hormone excretion during the child's development, but there would seem to be no striking changes from infancy to puberty. Some parts of the pituitary, the adrenal cortex, and the gonads do not function until puberty, but others are secreted in proportion to the size of the growing child. The 11-oxysteroids of the adrenal cortex, believed to be concerned in the response to stress, are produced from birth onward at the same intensity as in the adult, per surface area. The 17-

ketosteroids, mostly end products of androgenic hormones from the adrenal cortex and gonads, make a surprising appearance around about nine or ten years in both male and female children and some have termed this the "adrenarche." The nervous pattern of copulation and orgasm is complete by early childhood but not normally stimulated into action until the sex hormones are secreted and lower the threshold to stimuli. More is known about the electrophysiological developments in the brain during latency. The slow or delta activity declines sharply during the preschool years and is not a prominent feature of the juvenile record as far as amplitude and abundance of activity is concerned. According to Grey Walter, it persists (statistically) in docile, manageable, and easily led children whom he terms "ductile." These children tend to drift inevitably into delinquency. The theta rhythms are characteristically prominent during early latency and are easily evoked with frustration. The decline in theta parallels the decline in temper outbursts in preschool children, and its association with the frequent annoyance and deprivation of the preschool period suggests the reason for its relative inactivity during the latency phase. Its presence has been linked to the level of emotionality in the individual. The alpha rhythms attain their adult distribution sometime between the ages of nine to eleven, but the variations may be considerable. There are juveniles who show no alpha rhythm at all and others in whom it persists throughout the waking day, whether the eyes are closed or open, and whether the child is concentrating or relaxed. The rise

of alpha may have something to do with the child's new orientation to his environment during latency and his attempts to reduce its diversity to regular, recognizable, and familiar patterns.

Emotional development does not settle until later in latency. Gesell depicts the emotionality of the younger juvenile and the marked disequilibrium between him and others in his environment. He is given to extremes of expression, to love and hate, and to extreme sensitivity to praise and blame. He is fearful during these early years, especially of the supernatural, of animals, of self-injury, and of something dreadful happening to his mother that may take her away from him. His dreams reflect these same concerns, and girls especially may fear and dream of men getting into their rooms and attacking them. In the later part of latency the emotions are brought more under control, and the juvenile is in much better equilibrium with others. Whereas in the early years he was somewhat humilious and unamenable to management with humor, later he is able to develop a good sense of humor and can even laugh at himself. The later fears tend to be realistic and concerned with school problems, competitive situations, and worries about failure, and although far fewer dreams are reported in the later part of the period, they mostly have to do with experiences regarding possessions, playmates, and personal difficulties or worries connected with these.

These are, of course, group profiles drawn by Gesell of white middle-class children, and they say very little about children in general, children in different cultures, children under conditions of disadvantage, children with different constitutional propensities, and individual children. The self of this white middle-class juvenile undergoes changes highly reflective of the child-centered world to which it belongs. In early latency Gesell describes the self as the center of its universe, expansive, undiscriminating, self-willed, and demanding to be first, to be loved the best, to be praised and to win. At times the self may even seem to inhabit "another world" and to withdraw into this whenever circumstances are not propitious. There is also a self-consciousness about the body and the beginnings of modesty, especially in the girl. Shame is a powerful affect stemming from lapses of competence. Later, from nine onward, the child seems gradually to change for the better, to be more outgoing, more social, more interested in relationships especially with other children; more independent, self-sufficient, dependable, and trustworthy; more responsible and much busier and more actively interested in school work, hobbies, and a variety of tasks. At this point he becomes a "worker" and may even prefer work to play. He is increasingly self- aware about what he does, what he is, and what he can and cannot do. He is likely to complain a lot about life in general, his life in particular, and the way in which his body is malfunctioning. At the end of the period he may become markedly hypochondriacal and fearful of death and may even experience an existential

crisis.

He now belongs almost completely to the society of children, and although living within adult society, he picks his way through it preoccupied with the concerns of childhood. He is part of a special, separate subculture with its own traditions, rules, regulations, values, and loyalties, and like primitive cultures it is handed down largely by word of mouth from child to child. In this proving ground the child learns to function apart from adults and practices a variety of roles both in play and in social interaction. For the younger child play especially represents a time out in which he allows himself to escape from the limitations of reality and to undergo, if only momentarily, in Sully's term, a "transmutation of the self." He often plays as industriously and as seriously as he works, and since he is still reverberating from the emotions of preschool, he may use play further for catharsis, wish fulfillment, fostering anxiety, problem solving, circumventing the conscious, symbolizing conflict, stimulating new identifications, softening the impact of trauma by repetition, and elaborating new systems of defense. In the latter part of childhood participation in games teaches him to compete, to win and lose gracefully, to eschew cheating, and to cooperate with his peers. As a member of his group or gang he may take his place in the pecking order and construct a fairly valid concept of himself in terms of his usefulness to the group, capacity for leadership, and organizational skill. The membership carries with it the joys of belonging and the pains of exclusion or ostracism. Neighborhood

groups are subdivided by age and sex, and in stable residential areas there may be direct continuity between early childhood groups and the street-corner society of preadolescence and adolescence. Some of the groups maintain their organizational identities while successive generations of children pass through them.

At this stage it is usual for the two sexes to play separately, although they may still share in the same interests and even play the same games. Few latency girls are likely to participate in predominantly male games, but practically no boys ever openly engage in what are thought of as female ones. However, the interest of the two sexes shows convergence, and the sex cleavage is no longer as absolute. In the gangs a good deal of sexual experimentation may take place, and heterosexual exploration at this age is also becoming commoner as parents countenance or promote mixed parties. The continuity of sex role, to use Benedict's expression, is more manifest for girls who may spend a large part of latency rehearsing for motherhood, homemaking, and child care. Only a few adult occupations are continuous with boyhood culture.

There is no doubt that siblings provide an intense and crucial "corrective emotional experience" for the child and although the contacts are likely to be, according to Stone and Church, marked by "baiting, bantering, bickering, battling, belittling, and bedlam" within the family, an extraordinary

solidarity may prevail outside it. The children hand down clothes, toys, traditions, customs, and play patterns from one developmental stage to the next, and they model for one another in terms of appropriate sex and age behavior. The world of parents is gradually left further and further behind although they are still a central pivot in the child's life. He may boast of their achievements, demand their backing and enthusiasm in his pursuits, and still appeal to them as the final arbiters where sensitive matters of justice and fairness are concerned. Nevertheless, deidealization is gradually progressing, and the child is becoming increasingly aware of his parents as fallible and sometimes frail human beings.

Psychosexual Development (Freud)

The primary psychoanalytic concept relevant to the juvenile period is that of sexual latency. Latency begins with the resolution and repression of the Oedipus complex and ends with its reactivation at puberty; it is a kind of psychosexual moratorium in human development that allows the future adult to learn the technical skills necessary for a future work situation. This is different from the psychosocial moratorium given by some cultures to the adolescent so that he can find a place for himself in society. The first moratorium is brought about by mechanisms of repression and sublimation, and the second by suppression and prohibition. In our Western culture latency children manifest a great show of indifference and even antagonism

toward members of the opposite sex, and such reaction formations are further rewarded by the attitude of society in general. The upsurge of intellectual curiosity observed in schoolchildren has been ascribed to sublimation, to transformations of repressed sexual energies, and also to disguised sexual curiosity. The rules and rituals of this stage are also seen as magic devices for controlling impulses and feelings, including the anxieties and hostilities derived from the oedipal conflict. Latency children, with their superstitions, their collecting and hoarding habits, their mysterious chants and formulas, show a slight resemblance to patients suffering from an obsessive-compulsive neurosis, and latency children will often complain of compulsions, thoughts, and snatches of music that they cannot be rid of, magical counting devices before test situations, and sometimes quite elaborate systems of checking and undoing. All these are still within the range of normative development and the symptoms disappear with the stage. The compulsions may be a means of giving the child some sense of security, certainty, order, and meaning following his escape from the chaotic and confusing experiences of the oedipal period. Since no conflicts can be perfectly repressed, some of the child's rituals represent a disguised, symbolic enactment of an impulse escaping the repression barrier. Therefore, the characteristic latency child is a mildly obsessional child whose compulsions are very likely to pass with the onset of puberty.

Questions have been raised about how latent the situation really is, and

investigators such as Broderick have pointed to the amount of heterosexual as well as homosexual interests and play in the preteen years. He feels that sexuality is still active but simply hidden from adult attention. Forbidden information, "smutty" magazines, crude drawings, dirty jokes, bad words, medical diagrams are passed around the underground with a great deal of nervous excitement and pleasure. Curiosity is probably stronger than craving at this age and the toilet function inseparable from the sexual one. In children who have been overstimulated or seduced, a greater degree of precocity may develop and at the same time provoke much anxiety. The main repression, according to psychoanalytic theory, is directed toward sexual feelings for the parent of the opposite sex, and it is this element that is universally latent. The Henrys have furnished us with protocols from the doll play of children in an Indian tribe, and the record is replete with gross references to copulation. The latency children in many primitive societies spend a lot of time in sexual acting out under the permissive aegis of the elders, and Harlow has pointed to the fact that sexual play among immature rhesus monkeys is essential to sexual competence in adult life. The rehearsal of sexual elements becomes increasingly proficient with practice.

The drives that made the preschool child dream and play undergo sublimation into a host of latency activities, the most important being the sharpening of the epistemological interest. The child becomes a glutton for knowledge as his sexual curiosity is transformed into scholarly

inquisitiveness. Leftover anxieties are dealt with by a wide range of defenses characteristic of the latency child and manifest themselves in minor phobias, obsessions, compulsions, conversions, and depressions, all within the normal range. Shame in reference to real or imagined inferiorities and guilt in relation to masturbation and masturbatory fantasies may push the latency child ever closer to a manifest neurosis. Infantile sexual theories are further embroidered and changed following research in latency, but it is surprising, even with systematic sexual education, how fantastically the process of reproduction can be perceived. But as Freud pointed out, many erroneous ideas are invented by children in order to contradict older, better, but now unconscious and repressed knowledge. Furthermore, the latency child may admit that all parents, except his own, may copulate in the manner described by his instructor: "It is possible that your father and other people do such things, but I know for certain that my father would never do it."

Two fantasied offshoots of the Oedipus complex in latency are, first, the beating fantasy, which has its origin in the girl's incestuous attachment to the father or the boy's feminine attitude toward his father, and second, the family romance, which represents a stage in the estrangement of the child from his parents. In early childhood he may feel that he is not getting his full share of parental love and attention, and he may develop the idea that he is a stepchild or an adopted child. Somewhat later he may invent parents of higher social status. When he has become aware of the sexual determinants of procreation,

the family romance undergoes a "peculiar curtailment"; the father becomes a stranger and exalted but the mother remains the same, although in dreams they remain king and queen. In one of his papers Freud reproduces a letter from a motherless girl of 11 years who urgently asks her aunt the "truth." "We simply can't imagine how the stork brings babies. Trudel thought the stork brings them in a shirt. Then we wanted to know, too, how the stork gets them out of the pond, and why one never sees babies in ponds. And please will you tell me, too, how you know beforehand when you are going to have one." (The writer of this touching request has developed a compulsive neurosis full of obsessive questioning.)

Psychosocial Development (Erikson)

The central concept in Eriksonian developmental theory is the epigenesis of identity, the slow unfolding of the human personality through a succession of psychosocial crises or turning points. In this system the child enters latency, if all has gone well, with a requisite measure of basic trust, of confidence (Benedek) , of mutuality, of autonomy, and of initiative, all contributing to his overall rudimentary sense of identity. According to Erikson, identity is one of the "indispensable coordinates" of the life cycle and emerges more firmly, more completely, and with an increasing sense of inner unity with each crisis that is encountered and mastered. Each turning point in the epigenetic ground plan represents a period of specific vulnerability, a

concomitant shift in instinctual urges, and a new interpersonal perspective. The child who is a developmental success actively masters his environment and begins to perceive himself and others more correctly. When development is failing, the child comes into latency overwhelmed by mistrust, shame, doubt, and guilt. Trust is the cornerstone of the healthy personality and stems from transactions with a trustworthy mother, imbued with a sense of fairness and justice. She has also been able to inculcate a deep and almost "somatic" conviction that there is meaning to her management of the child. The psychosocial issue of trust to mistrust is a crucial quotient for the rest of the development. In latency the child is confronted with a widening social radius, expanding libidinal needs, a large number of developing capacities, and a specific psychosocial strength deriving from a favorable trust- mistrust ratio.

Erikson believes in the essential "wisdom of the ground plan" so that when the child reaches school age following the expansive period of the preschool years, he is more than ready to get down to work and discipline himself to perform well and to share in whatever is being constructed and planned. He becomes a manufacturer, a producer, a tool user and occupies himself industriously with making things as perfectly as he can and persevering with the job until it is fully done. When things go wrong, on the other hand, feelings of inferiority can develop, especially when he persists in comparing himself unfavorably with his father. A great deal depends on the parental surrogates who step into the picture to continue the work of the

parents. The good enough teacher knows how to alternate work and play, recognize special efforts, and encourage special gifts. The good enough parents encourage their children to trust their teachers. The good enough school is not simply an extension of grim adulthood and the puritan ethic into the classroom or an extension of the expansive imagination of childhood without restriction, but something of both. The contribution, therefore, of the school age to the sense of identity can be expressed in the words: "I am what I can learn to make work." To many children this is also the end of identity and its consolidation around an occupational or technical capacity. This is a foreclosure of identity and abrogates the "higher" elements of identity.

Interpersonal Development (Sullivan)

Sullivan constructed a heuristic classification of personality development ranging from infancy to adulthood and governed by the central principle of interpersonal cooperation. In this scheme the juvenile era begins with the need for playmates, defined as cooperative individuals of comparable status, and ends with the need for an intimate relationship with a single person of comparable status. Sullivan reiterates many times that this particular era is of special importance since it constitutes the first occasion when all the drawbacks of living in the family can be remedied in the world outside the home. It almost seems as if Sullivan is implying that one stage of development can be therapeutic for another, and if this is at all true it

emphasizes the need to study the developmental stages in parallel in order to be able to exploit this ameliorating capacity to the full. Sullivan suggests that unless the juvenile era can alter the spoilt or self-effacing child for the better, he is going to be increasingly impossible to live with and work with in later life. (It is well to remember that Sullivan was particularly inclined to express himself in somewhat exaggerated terms and that most of his assertions need to be toned down to some extent.) At school the child is required to subordinate himself to new authority figures with whom he has often had minimal experience. In order to get along in the new milieu, the juvenile must learn some degree of social accommodation, which is mainly a principle of expediency. However, social accommodation has the effect of increasing social competence as well as providing the individual with a basic education in getting along, getting by, and getting away with things. With increasing social sophistication the juvenile is able to detoxify the frightening authority figures and reduce them to the proportion of people. Without such necessary de-idealization the parents and their homologues remain sacrosanct and the juvenile continues in servitude.

Therefore, the juvenile era is the time, as Sullivan puts it, "when the world begins to be really complicated by the presence of other people" in relation to whom there must be cooperation, criticism, competition, compromise, concentration of attention, and real interpersonal communication. As a result of all these, the juvenile learns a good deal about

how to create a secure environment for himself. The self-system at the core of Sullivanian personality development is a dynamism that organizes experience, controls the content of consciousness, and deals with the intrusion of anxiety. It is not synonymous with the psychoanalytic superego, although it sounds like it at times. Sullivan does little to clarify these overlapping terms and tends to avoid the issue. "It has been so many years since I found anything but headaches in trying to discover parallels between various theoretical systems that I have left that for the diligent and scholarly, neither of which includes me."

Another piece of learning that goes on during the juvenile era is "sublimatory reformulation," which consists in substituting acceptable behavior for unacceptable behavior for the sake of appeasing authority figures. Since this diminishes gratification, the unsatisfied need must be worked off in a dream or daydream.

Since life at this time is largely lived in groups, the question of belonging to outgroups or ingroups becomes a crucial factor for healthy development. It may be hard for the juvenile to understand the mysterious workings of segregation and ostracism, and no amount of wishful thinking can transform an outgroup into an ingroup. Self-esteem is one of the major casualties of the group organization of the juvenile world. In addition to grouping, the individuals at this stage also resort to stereotyping, and if this becomes fixed,

it can give rise to real trouble later on. A great many juveniles arrive at preadolescence with quite rigid stereotypes about the classes and conditions of mankind. These troublesome stereotypes also invade the self-system and set up "supervisory patterns" in the processes and personifications that constitute the self-system. These imaginary people are always with one and can be hearers (judging the relevancy of what one is saying) or spectators (of what you showed to others). Since these act in an inhibitory way, they can be compared to the psychoanalytic superego and ego ideal system. The supervisory patterns come into being in the juvenile era and form a part of the elaborate organization for maintaining self-esteem and self-respect.

As the individual reaches the end of the juvenile era, he gains, whether he likes it or not, some sort of "reputation" in terms of popularity, sportsmanship, brightness, and other desirable or undesirable attributes. If one leaves the juvenile era with a bad reputation, it is likely to stick to one and prove a handicap during further development.

The individual is not only subjected to influences from the peer group but also from the parent group, and one of the less fortunate things that parents can do at this stage is to teach disparagement. As Sullivan puts it in his usual vivid style, "the disparaging business is like the dust of the streets— it settles everywhere." It can be very disastrous for the individual if the only way he can maintain his self-esteem is by pulling down the standing of others.

Security achieved in this way is not real security and can easily crumble.

By the end of the juvenile era, all being well, one becomes "oriented in living" or, put in another way, "well-integrated." The integration includes one's interpersonal relationships, their management with relatively little anxiety, and the capacity for postponing immediate gratification in favor of some eventual gain. The juvenile who is well oriented to living has a more or less assured future; the juvenile not so oriented is destined to be, to use some of Sullivan's favorite negative epithets, "unimportant," "troublesome," and a "lamentable nuisance."

Psychocognitive Development (Piaget)

The juvenile period, on Piaget's scale, approximates the end of the representational period and the stage of concrete operational thinking. Egocentrism is on the wane throughout the stage. Symbolic play gradually disappears, to be replaced by games. The child's conception of the world is gradually approaching the adult one.

At first glance there would appear to be some similarities between Piaget's and Gesell's notion of development. As Hunt has pointed out, both employed the cross-sectional method of confronting children of various ages with situations and materials, at the same time observing how the children reacted and responded; both described behaviors typical of children at

successive ages; both recognized an epigenetic system of change in the structure of behavior as essentially predetermined, although Piaget is more of an environmentalist and his conception of the organism includes a theory of adaptation governed by the input and adjustment mechanisms of assimilation and accommodation. As a "stage" psychologist, Piaget has postulated a definite order in development, a succession of more or less self- contained stages, with an intrastage hierarchical organization of attributes and transitions from one stage to the next. Anthony has suggested that a system such as this with well- defined stages, transitional periods, and a dynamic adaptation theory could well provide a basis for a psychopathology.

Egocentrism is narcissism without Narcissus or self-awareness. The process of differentiation between the ego and the world is still incomplete. The child is at the center of the universe, and his perspective is subjective, absolute, and incapable of allowing for another viewpoint. Early in the juvenile period a revolution in perspective takes place, and the child sees himself as a thing among many other things in the universe and by no means the most important of them. This is something in the nature of a Copernican shift. From being highly subjective and absolute, the viewpoint becomes objective and relative, and for the first time the child becomes capable of getting himself in someone else's shoes and perceiving the world through the other's eyes. However, by six or seven years he is not wholly free from egocentrism, and his world is still alive in every part with animistic

projections and magical-phenomenistic forces. The sun and moon follow him around; his dreams come in through a window at night; a stone will feel a prick if it is rolling; twisted string unwinds itself because it feels all twisted up; shadows arc emanations from objects; and so forth.

As logical, operational thinking takes over, even if tied exclusively to the manipulation of concrete objects, this dynamic, primitively conceived world sobers down and becomes much more realistic and down-to-earth. The child gives up thinking by transduction and juxtaposition of ideas and is surprisingly capable of conceiving reciprocal relationships and reversing his thought processes. Revers- ability is the crucial cognitive achievement of the juvenile era. Not only does the child think more logically, but his previously egocentric speech, seldom more than a "collective monologue," becomes socialized and intended for communication. In fact, his whole approach to his environment becomes less amorphous and syncretistic and more precise and differentiated. His cognitions can now encompass a variety of mental transformations referred to as groupings (a logico-mathematical structure that Piaget finds useful for describing cognitive operations). As a result the juvenile can solve many problems that lie beyond the capacity of the preschool child. A child from seven to eleven years behaves as though his primary task consists of organizing and ordering what is immediately and concretely present before him. He is essentially a here-and- now child, and what is absent or what is potential is not his concern. He is bound to the

phenomenal and engages the elements of his universe one by one in his efforts to master them. He learns about classification, serialization, conservation, inclusion, the dimensions of time and space, and basic notions of movement and velocity, all of which help to make him familiar with the workings of his environment.

What drives the child to all this accomplishment? According to Piaget, it is because he has to "nourish" his internal cognitive schemata by repeatedly incorporating nutriments from the environment. There is a need to function, which is the only motivation that Piaget recognizes. Furthermore, the child's feelings are not tied to his motivations but to his cognitions and undergo a parallel development that is simply the reverse side of the coin. The intellect furnishes the structure and the affect provides the energy. During the juvenile era, the emotional life is isomorphic to the logico-arithmetic organizations and is characterized by highly structured systems of values, concepts of justice and obligation, fairness in transactions, and interpersonal relations founded on reciprocity and individual autonomy. The "two moralities of childhood" stretch across the whole juvenile period. The first morality, during the earlier years, is authoritarian and based on constraint and unilateral respect. Games are governed by coercive rules that are absolute and inflexible, and moral judgment derives from external and heteronomous sources. There is a moral realism about crime and punishment and the need to fit them together literally, so that a child who breaks six glasses is twice as

culpable as the child who breaks three and must be punished twice as harshly. Punishment is dictated by the *lex talionis.* No one can escape justice; it is immanent in the entire universe, so that a child who has been stealing apples may very well break a leg as he attempts to escape over a wall. In the second part of the juvenile period, morality is based on norms of reciprocity involving cooperation and mutual respect. Games are governed by rules agreed upon by the participants, and the sense of fairness may extend even to the point of making allowances for natural inequalities. For example, the child who has an injured knee will be given a handicap in the race. The moral sense is now internal and autonomous and functions even in the absence of authority figures. The justice meted out is "distributive," which means fairly apportioned in terms of responsibility.

The Possibilities and Problems of Synthesis

Taken in totality, the picture of juvenile development by Gesell, Freud, Erikson,- Sullivan, and Piaget, combined with the empirical findings of academic developmental psychology, is rich, complex, and varied. The different systems do not articulate very closely, nor do they agree very often on the interpretation of similar behavior, but they do frequently seem to be saying similar things in different ways. The language of the systems is idiosyncratic, and this in itself creates a climate of difference. The juvenile child turns away from his family and from his egocentric self to a society of

peers with whom he engages in various cooperative transactions that are governed by principles of reciprocity and equality. Because of the physical and psycho- sexual latency, he can use a lot of his energies for epistemological ends and gradually constructs an internal representation of the world that is fairly authentic and based on reality. He talks now in order to communicate, and his concrete thinking allows him to categorize his world, though to a mildly obsessional extent. He lives and works in groups and attempts to conform to the group's code of behavior; he is miserable when excluded from the group. He is on the way to developing a full and consistent identity and a sense of self that gives him a feeling of continuity throughout all the vicissitudes of developmental change. The self, which has private and public components and both true and false aspects, may emerge into self-consciousness suddenly and dramatically at the end of the juvenile era.

The Preadolescent Period

Definition

The end of childhood is indefinite since puberty may intervene almost any time after the tenth year. Educationally the largest number of preadolescents are concentrated in the junior high schools between the seventh and the ninth grades. Preadolescence can therefore be defined as an indeterminate period of variable duration, but mostly brief, between the

eleventh and the fourteenth year. It is the transitional period between childhood proper and maturity. Many developmental psychologists ignore its existence; some give it a passing reference, while others, like Sullivan, speak impressively of its significance. He refers to it as "an exceedingly important but chronologically rather brief period." For Piaget formal or abstract operational thinking makes its first appearance during this era, and with it a new conception of the world unfolds.

The term "pubescence" refers to a period of about two years immediately before puberty and to the preparatory physical changes that take place in this time. Its onset is marked by a prepubertal growth spurt signaling the end of growth latency, and along with this comes changes in the facial and body proportions, the appearance of primary and secondary sexual characteristics, and a variety of other physical changes that may sometimes persuade the child that he is turning into a completely different person. In both sexes the extremities and neck grow at a faster rate than the head and trunk, giving the self-conscious youngsters the long-legged, gawky, and coltish look characteristic of this age. The shoulders broaden in the boy and the pelvis widens in the girl, who, to a greater extent than the boy, develops a layer of subcutaneous fat that rounds and softens the contours of the body. In general, the boys remain leaner and more angular. The growth of pubic, axillary, facial, and chest hair adds to the transformation. The skin becomes coarser, the pores larger, and the sebaceous glands more active, and as a

result the young person becomes subject to the miseries of acne. The composition of the sweat also alters and the odor becomes stronger. This, together with the odor of menstruation, intensifies self- consciousness. In girls the areolas grow larger and become elevated and pigmented, and the breasts may attain almost full size prior to the menarche (according to Aristotle, menstruation tended to begin when the breast was two fingers abreast in size). A typical feature of pubescent physical development is asynchrony in the development of bodily parts. (Stone and Church referred to this as "split growth.") The resulting asymmetry may further intensify the child's feeling of being "off kilter" and this, together with early and late maturing, may promote transient maladjustments in the preadolescent. (These effects may be more permanent than was previously supposed. Jones has shown that personality differences between early and late maturing individuals may persist well into adult life. Early maturers as a group were poised, responsible, successful, and conventional, and late maturers were active, insightful, independent, and impulsive.)

The functioning of the endocrine glands during this period of growth and development provides an example of "feedback control," in which pituitary hormones stimulate adrenal hormones, which, in turn, stimulate gonadal hormones, which then inhibit the pituitary hormones and cause secretions to slow down. As a result of this, the pituitary-inhibiting secretions of the gonads also slow down and the pituitary once again becomes active.

Why the pituitary becomes active at this particular time is not known, but it is thought to be part of a genetically programmed pattern of normal maturation.

Psychologically the preadolescent individual is more akin to the latency child than to the adolescent.

Psychosexual Development (Freud)

The new developments in the physical system create new feelings and new urges in the psychosexual sphere, with some increase in sexual tension. However, the mechanisms operating in the latter part of latency undergo a complementary increase in strength, so that the child's ego may become more heavily defended than at any other time during his development. Some analytic therapists insist that the child is more difficult to treat at this period than at any other and that transference work is particularly hard to carry out.

If one looks at the middle years in terms of defense, there are marked changes in the picture presented. During the first phase of latency the new superego is harsh, rigid, and, according to Bornstein, "still a foreign body." Two different sets of defenses begin to operate. The first is directed against the genital impulses and leads to a temporary regression to pregenitality, which seems at first to be less dangerous, but later offers problems of its own and provokes a second defense against pregenitality that is largely reaction formation. This brings about the first character change in latency. As a result

of increasing genital pressure and constant defense against it, the child becomes increasingly ambivalent and oscillates between obedience, rebellion, guilt, and self-reproach. There is little he can do during this "intermediate stage of superego development" (Anna Freud) except to identify with the aggressor or project the guilt. The whole equilibrium is extremely precarious, and every now and then a crisis situation occurs that may manifest itself in acute symptoms such as animal phobias, fears of being hurt or dying, insomnia and nightmares, and sometimes a new wave of separation anxiety. In the second phase of latency things are not as smooth as often described. Adults especially, when recalling latency, seem to be conjuring up the "ideal of latency" during which the instinctual demands have been successfully warded off. There is some truth, however, in the assertion that infantile neurosis decreases during the second part of latency. Certainly the sexual demands seem less pressing, the superego less rigid, the ego more preoccupied with reality, and masturbation less frequent. The gradual de-idealization of the parents helps to attenuate conflict between ego and superego. Because of the resurgence of instinctual forces accompanying pubescent development, the defensiveness of the preadolescent has become a therapeutic byword. The child is caught between latency and pubertal struggles, between old and new sexual aims. The latency peer relationship is now reduced to a group of two with homosexual undertones. As a result mutual masturbation and other sexual practices may erupt from time to time, associated with shame and

guilt. A recapitulation of the psychosexual development of the first five years may come into evidence toward the end of the preadolescent period.

Psychosocial Development (Erikson)

Erikson has very little to say about preadolescence, and it does not figure as a separate "box" in his epigenetic diagram. It is difficult to explain this oversight on his part, since the child obviously does not jump from industry into the confusions and turbulences of adolescence without some transitional or prodromal experiences. He clearly believes that at each stage the child becomes a very different person with greater capacities for action, reaction, and interaction and that the psychosexual moratorium is there for the specific purpose of learning the basic grammar of the culture during the sexual lull when the polarities of industry and inferiority are operating and competence begins to emerge.

Interpersonal Development (Sullivan)

Sullivan has much to say about preadolescence and what is for him the primary characteristic of the period, which is the preadolescent collaboration, different in every way from the cooperation, competition, and compromise of the juvenile era. The developmental force that brings this about is the integrating tendency, otherwise known as love or the need for interpersonal

intimacy. This is a specific new type of interest in a *particular* member of the *same* sex that eventually develops into what Sullivan calls a "chumship." What he is saying is that real love begins in preadolescence and that all previous relationships during development with peers and parents are essentially exploitative rather than reciprocal. In the loving chumship of preadolescence each partner moves toward the other for the purpose of mutual satisfaction. This special sensitivity with regard to the other person and his feelings is the hallmark of this stage. As Sullivan puts it: "Collaboration is a great step forward from cooperation." A change takes place from predominantly me-feelings to we-feelings. Because of the intimacy and the new capacity for seeing oneself through the other's eyes, the preadolescent phase of personality development is especially significant in correcting autistic and fantastic notions about oneself or others. Here again Sullivan puts forward his fascinating idea of a developmental stage being therapeutic for disturbances inherited from other stages. "Development of this phase of personality is of incredible importance in saving a good many rather seriously handicapped people from otherwise inevitable serious mental disorder." Here he isn't allowing for his usual liberal use of superlatives. This idea would seem to be something that every therapist should keep in mind, involving, as it seems to do, a synergism between natural and artificial therapy. The essential therapeutic ingredient in the preadolescent phase is the "chumship."

The gang at this time is basically structured on the two-group

interlocking with other two- groups. Another basic unit is the three-group, made up of a two-group and a preadolescent providing model qualities to the other two. Thus, there is a lot of mutual influencing in the gang. When the members are confronted with serious problems that overwhelm them, one of the "models" may assume the role of leadership for the purpose of solving the pressing issues. The preadolescent personality is therefore molded by this developing leadership-led system of relationships. Another important aspect of the gang is that it provides, for the first time during development, what Sullivan refers to as a "consensual validation of personal worth." The improved communication between chums helps to rectify the self-deceptions and mythologies. The intimacies of preadolescent socialization may also help to correct the leftover egocentrisms of the juvenile era or the marginal case, constantly on the fringe of ostracism, who may have been in the outgroup of juvenile society. Sullivan pooh-poohs the alleged dangers of homosexual development and feels that the chumship is a marvelously corrective emotional experience for the bad sports and spoiled children emerging out of the juvenile era. He is shocked by the idea that preadolescence could be considered as a training for an antisocial career because of the gang influence. He agrees that in bad circumstances and bad environments there are likely to be bad gangs, but even in these extreme cases the gang experience can be of value for socialization. So therapeutic is this phase in Sullivan's eyes that even juveniles entering preadolescence with what he calls a "malevolent

transformation of personality" may have this ameliorated, reversed, or even cured. The juvenile who has a vicious disparaging tendency that constantly pulls people down may also have this somewhat mitigated by the preadolescent experience. Schizoid individuals may also benefit, although there is a chance that their self-isolating behavior may make it difficult to establish the type of intimacy required for a chumship, and puberty may be established before they can reap the benefits of the period. The persistent juvenile who tries to avoid growing up may eventually wend his way into an irresponsible gang unless he can be salvaged by a chumship. The handicapped child is particularly likely to suffer from the competitions and rivalries of the juvenile era, but he may come into his own with the development of preadolescence and the helping hand of a chum.

The two-group has its built-in disadvantages as well as advantages. If the relationship is too intense, fixation in preadolescence may occur or homosexual developments might take place. Once again Sullivan dismisses this risk and insists that his own hope would be that the preadolescent relationship was intense enough "for each of the two chums literally to get to know practically everything about the other one that could possibly be exposed in an intimate relationship." It is difficult to know exactly what he means by this, but he clearly is proclaiming his faith in the "great remedial effect of preadolescence." At times like this he does seem perilously close to pushing a pathological development, and it is possible that wide experience of

the adult outcome has provided him with the confidence for such assertions. What is sometimes disastrous for the preadolescent chumship or gang is unevenness of development at this time, which puts the participants out of phase and sometimes out of relationship with each other. Bad couplings may result from preadolescents' linking with those still juvenile or those already pubertal, and in these situations homosexuality or schizophrenia are possible risks. The different time schedules of development bring about differences in attitudes, values, and behavior that carry with them the seeds of disruption.

In preadolescence, where real intimacy first begins, there can also be bitter experiences of ostracism and consequent loneliness. Without the protection of intimacy, loneliness can be terrible, and it is in this era that loneliness reaches its full significance and goes on relatively unchanged for the rest of life. The defense against loneliness is what shapes existence.

Psychocognitive Development (Piaget)

In Piaget's system a cognitive revolution takes place in the preadolescent. His reasoning frees itself from the concrete and begins to undertake such formal operations as deduction from hypotheses. A final state of equilibrium is reached at about 14 to 15 years. The preadolescent also starts to construct theories and make use of the ideologies that surround him. Piaget links these new capacities to the development of neurological

structures and suggests an isomorphism with them, as do the Gestaltists. Nevertheless, he also is aware of social and cultural influences and feels that education may accelerate individual development. As he says, the maturation of the nervous system can only determine the totality of possibilities and impossibilities at a given stage, but the social environment remains indispensable for the realization of these possibilities. This constant circular process characterizes all exchanges between the nervous system and society, and the individual has to learn to adapt to both physical and social worlds.

The preadolescent differs from the juvenile in that he thinks beyond the present and commits himself to possibilities. Unlike the juvenile, he begins to build "systems" as well as to think systematically. The juvenile does not try to systematize his ideas and is not reflective or self-critical. The preadolescent can also make theories, although they tend to be oversimplified and awkward at first. He may also develop theories as part of his intellectual life with the gang. He is not only capable of thinking about the past, the present, and the future, the present and the absent, but he is also able to think about thinking, which is another leap forward in self-consciousness.

What Piaget calls the third form of egocentrism emerges at this stage and continues through adolescence as one of its most characteristic features. It is only when this is "decentered" that a true adult work orientation becomes possible. The egocentrism of the preadolescent still makes him try to

adjust the environment to his ego rather than the other way about. As a result there is a relative failure to distinguish between his own point of view as an individual and the point of view of the group. The preadolescent society helps to mitigate and correct this perspective. This egocentrism allows the preadolesccnt to attribute an unlimited power to his own thoughts, so that he dreams of a glorious future of transforming the world through ideas or reforming the present sorry state of affairs. All this is generally fuzzy and contains elements of play rather than serious work.

One should point out, if it is not already sufficiently apparent, that Piaget does not have an adequate personality theory. In a somewhat oversimplified way he sees the ego as naturally egocentric and personality as a decentered ego. This is not enough to construct a personality theory and certainly not enough to make a psychopathology.

Conclusion

Preadolescence is, therefore, a gateway to adolescence; it is the crucial transitional era between the juvenile and adolescent stages; it is a time for high defensiveness, for intimate chumships, for therapeutic relationships, for the flowering of a new and important kind of human intelligence whose eventual purpose is to shape the future of the world. It is there to repair all the disastrous damages of development and prepare the person for the new

and different world in front of him.

Chapter 18

Adolescence

Irene M. Josselyn

Adolescence Defined

The term "adolescence" is ubiquitous; as a result its use creates confusion for the reader unless it is specifically defined in the context of the discussion offered. In this chapter the term "adolescence" is used to describe the psychological stage in personality and character development that follows the latency phase of childhood.[1]

Prior to latency the child has, through adaptive and defense mechanisms, achieved some integration of his internal needs, urges, and wishes within the relatively circumscribed reality provided by his primary love objects. During latency this integration pattern widens, with progressive adaptation to an expanded reality and a meaningful social milieu. The typical latency child is occupied primarily with external realities to which he responds with relative predictability and minimal disturbance over crises. It

is not, as implied by the term "latency," a dormant period, but rather a span of time during which, optimally, the child's psychological gestalt is becoming enlarged and basically melded to provide a firm foundation for the next span of growth, adolescence.

During adolescence there is structured upon this foundation of latency what will become the architecture of the adult personality and character, as well as the crystallized potentiality for neuroses or psychoses. The analogy of the architectural structure is not chosen lightly. No total foundation is sound unless the bricks and mortar that are the fundamental components of that foundation arc sound and discreetly interrelated. Thus, latency is not optimally effective as a step toward maturation unless prelatency components have reached a constructive solution. Any seriously faulty solution of prelatency conflicts will result in the latency phase being poorly balanced; in addition, that lack of balance will distort what occurs as the superstructure develops and will effect the completion of the architectural design, adulthood. While adolescence is the preadult phase from which adulthood will evolve, adolescence is affected by the foundation upon which it is built. It is important to emphasize that as the significance of the adolescent phase becomes more and more understood, it is not to be evaluated as independent of the past but rather, for good or bad, a superstructure upon that past.

As many have pointed out, adolescence had not been studied with any intensity until approximately the last 30 years. Even with the evolution of thinking regarding psychological development from birth on, for a long time the adolescent phase was ignored by most students of human psychological development. Outstanding exceptions to this were Aichhorn, Bernfeld, Healy, Hall, and in her early work, Anna Freud." Prior to their writings there were protests by some against youth and wonderment or despair about what the youth of that day would do to the future. For the most part it was presumed that if adolescence was ignored the idiosyncrasies would end. There was little attempt to understand why the phase existed and what it achieved.

Adolescence as a Phase of Development

In recent years there has been increasing interest in exploring the manifestations and significance of adolescence. From this study has evolved two diametrically different points of view. There are those who describe typical adolescence as a period of turmoil and confusion. This has implied to others a degree of pathology that they do not believe exists. The latter group believe that normal adolescence is not full of turmoil; they argue that those who indicate otherwise base their conclusions upon their study of manifestly disturbed individuals and therefore attribute to all the troubles of relatively few.[2]

The disagreement concerning the dynamics of adolescence may be related to terminology and emphasis rather than a basic contradiction. Every phase of psychological maturation has inherent in it new conflicting desires to be harmonized. During the process of resolving the conflict, there are transient episodes of clinging to the old; at the same time the strongest force in the normal individual is to thrust forward. There are also brief false steps toward the next phase.

Adolescence is a phase in development. No one would assume that the ten-year-old boy of today will be the same fifteen years from now; he will have "grown up." He will have grown from childhood to adulthood, having reevaluated many facets of himself and the outer world during adolescence. As he strives during adolescence to attain a satisfactory adult role, he does not just seek it in playacting as he did earlier; rather he seeks for an internal realignment that will be effectively automatic, self- expressive, and predictable, a new self gestalt. It is this striving to abandon childhood and attain adulthood that is adolescence, an inherent phase in maturation.

The Cultural Impact

These changes, while primarily self-initiated and the adolescent's own psychological task, are affected by the particular culture's definition of the adult's role. Many cultures define sharply the child's role and the adult's role;

the path from childhood to adulthood is well trodden and clearly marked. In contrast, in Western culture the child is only familiar with vague directions. His position is comparable to that of the pioneers who explored the West; they knew the way led west, but the miles between their familiar homes and the anticipated riches at the end of their trek were uncharted except for the vague guidelines of the sun and the stars. Children of Western culture know that adulthood implies certain privileges, and certain obligations, among them the freedom to choose on their own, within broad limits. Before the individual makes his ultimate choices, he reevaluates many concepts that he previously had uncritically accepted.

Problems in Evaluating the Adolescent

This reevaluation and ultimate mastery of an adaptation to a new internal and external reality may be manifested in a variety of ways. Many adolescents show no external evidence of psychological change. The process is gradual, and only when it is relatively completed do those who know him well realize that he is different from what he was as a child. Frequently the change is only apparent after a period of absence. A boy of this type goes away to college, and when vacations reunite the family he seems strange to his parents. He is, as the family vaguely describes it, more grown up. He also is aware of, and frequently uncomfortable about, the change, but he tolerates the stress until vacation ends.

Another group of adolescents cause concern for their parents and possibly their teachers. They are moody, at times manifesting a gratifying pleasure in living and at other times acting depressed, bored, or irritable. Any attempt to explore the latter difficulty frequently leads to the response, "I don't know, I just feel this way," or a curt, "Can't you let me alone?" School achievement may be less than in the past, or it may manifest the same sporadic shifts as the mood swings, with successes and failures occurring unpredictably. This group in particular are frequently still diagnosed as "just adolescent"; family and teachers are assured that "it will pass." This group is perhaps most secretive about its thoughts. For a variety of reasons the individual prefers to find his own solutions to the internal problems with which he struggles. Only when he feels overwhelmed by some aspect of his confusion does he suddenly confide in his parents or in an adult friend. When he does confide he may appear to be dramatizing and exaggerating his difficulties. This evaluation by another *may* be correct, but usually the normal adolescent is not dramatizing. He is actively aware of his discomfort and experiences transiently a sense of having entered a blind alley that suddenly appears to be sealed at both ends.

A third group of adolescents show the degree of their turmoil through their overt actions. It is this group that makes the news and arouses the apprehension of adult society. Its members seek to handle their own confusion by changing yesterday so that today will be the beginning of a

future in utopia. They are inexperienced, naive, and have too many contradictory goals to outline a program that adults can grasp or apply. At times they do find pseudoadults who, as confused as they are, may become their mentors. On the other hand, most of them are soon disillusioned by these pseudoadults, will talk with them but will not, except for a shorter or longer period of time, follow them. In the latter instance the adolescent has tried on for size the ideas the adult has expressed and finally, often after long consideration, decides those ideas do or do not fit.

There are adolescents that may or may not be a part of the third group mentioned above. Their behavior is grossly destructive. Whether an individual manifesting such behavior has a deep-seated core of faulty adaptation, and therefore a character defect or a serious psychological disturbance, only careful study over time will tell. They at least have a frustration tolerance that is too low for the frustrations they are experiencing. A certain number of them, either with help or by their own mastery of their inner turmoil, will leave this type of behavior behind them as they begin to resolve their phase-typical conflicts, and they will seek wiser ways to bring about constructive social, political, or personal change as adults. Others will undoubtedly become psychologically pathological adults.

The last paragraph illustrates the difficulty in evaluating "normal" adolescence. The behavior of adolescents, their verbalization, and often their

developmental history does not give a means of quick diagnosis of the syndrome they present." The first group described above may have among its members those who are preschizophrenic or actually schizophrenic, the symptoms masked by their slow, plodding attempts to deal with phase-characteristic adolescence. The second group may have among its members hysterical characters, incipient hysterics, or a manic-depressive constellation that will become manifest in adulthood. The third group may include those who in adulthood will still be psychologically young adolescents, remaining impulsive, intolerant of frustration, and unpredictable, or who will be sociopaths, schizophrenics, or delinquents. Any individual, irrespective of which group he appears to represent now, may develop later a mental illness that would appear more characteristic of a different adolescent type. Probably the soundest tentative diagnosis of normal adolescence is when, after a period of real communication with the individual, the adult becomes aware that the young person he is studying does not consistently fall into any of the above groups; rather he is shifting from one to the other and is at times immature, at other times strikingly mature, and, by adult standards, rational. This would suggest that the diagnosis "normal" is most valid when a diagnostician who knows adolescents, and who knows the prodromal symptoms of mental illness or of character defects, is confused about the proper diagnosis, the diagnosis being difficult because of the shifts that occur so readily in the constellation of behavior patterns and verbalizations—signs

that the adolescent is seeking to find himself.

Psychosomatic Nature of the Adolescent Emotional State

From one viewpoint the psychosomatic implications of adolescence are very clear. The onset of psychological adolescence is closely related to the increased function of the glands of internal secretion, particularly the reproductive glands. (The significance of those glands in relation to the spurt of growth prior to puberty will be discussed later.) The impact of the reproductive glands upon the emotional state of the individual is well illustrated in adults by various studies, such as those of Benedek concerning the menstrual cycle in women. The young adolescent of either sex, about the time that he attains physical puberty, becomes sensitive to things he either previously ignored, took for granted, or let pass. He is more easily hurt, more easily elated, more readily depressed, and more quickly angered over minor frustrations. His sensitivity also expresses itself in less egocentric ways. He reacts intensely to what is beautiful and to what is ugly, the former typically gratifying, the latter typically very painful.

He loves intensely and hates intensely. It is difficult for him to tolerate his ambivalent feelings. As a result he may love something or someone intensely until a minor defect becomes apparent; then, particularly in interpersonal relationships, he may hate as intensely as he loved. Similarly, if

he finds a positive element in the person or object that he has hated, he may reverse his attitude and abandon his hostility and temporarily only feel love. He is not completely unaware of this shift from positive to negative feelings. He often, particularly with people he cares for a great deal, finds his inability to handle his love and his anger, or his inability to accept imperfections, very confusing. This is especially so when he is aware that those toward whom he is reacting in this way do not understand and respond to each of his opposing feelings as if each erased the other. If others cannot harmonize his feelings, how can he? This is readily observed in an adolescent who has a basically sound relationship with his parents. At times he feels hostility toward them and can't understand why they are not the people he would love. Then later he loves them and can't understand why they don't believe that love.

It is important to bear in mind that the adolescent will not always manifest this confusion in feelings or indicate the intensity of either positive or negative responses to the beautiful or the ugly. Some adolescents deny positive feelings for people or for experiences that one would anticipate they would enjoy. Such denial, if indicative of an established attitude, would suggest pathology. While an apparently insensitive adolescent may be a disturbed adolescent, this evaluation is not necessarily true, particularly among boys. In our present culture the all-American boy, by adult standards, is supposed to be above expression of tender feelings, intense investment in beauty, and other emotional reactions that are experienced by young

adolescents. Boys therefore put up a veneer of indifference that is not necessarily how they really feel within themselves. One boy—who seemed in every aspect of his life to present a picture of a psychologically healthy adolescent-—-broke down crying after many hours of discussing his remoteness from his parents, "Gee, don't they realize I love them. I can't show it." If one accepted only his overt behavior of indifference to his parents, it was easy to see why they felt that he didn't love them.

This sensitivity in the adolescent is often the secret that they carefully shelter from the invasion of others. As disturbing as today's drug culture is to all adults, one thing can be learned from certain participants. Their underlying sensitivity to the meaning of interpersonal relationships and beauty, which is usually a well-kept secret, is revealed under the influence of drugs.

The psychological sensitivity that the adolescent is experiencing is new and therefore unfamiliar; he does not know how to channel it adequately into his future life. This sensitivity to his internal feelings explains in part why he works so hard to find a way to bring conflicting sensations into some sort of working order. Since such a process cannot be mastered by intellectualization alone, he is confused. As he recapitulates aspects of his early childhood, attempting to find new solutions, this sensitivity to his own confusion is always intermingled with his techniques for trying to attain a new self-image.

In his confusion society does not offer him a great deal of help; modern civilization offers very little sharply defined structure as a framework for the adolescent. Most of the advanced cultures of today are oriented to the importance of progress, not to a static society. This is particularly true of those societies based upon a democratic philosophy. Today a typical adolescent is confused by the teachings of democracy that stress the rights of the individual. While the adult recognizes there is a difference between freedom and license, many adolescents consider the differentiation quite hazy. It is difficult for them to understand why a statesman can make a statement that, if used in a school theme, would result in a threat of suspension from school! They cannot see the interrelationship of the total forest because they are able to grasp only one tree at a time.

The Ego Ideal and Superego during Adolescence

If adolescence is a normal step in maturation, what are the goals and conflicts characteristic of that developmental stage? Many explorers of this question have stressed the identity crisis as the chief characteristic. Prior to adolescence the child had found his identity, but it was his identity as a child. During normal latency he lived and enriched that identity. With the advent of psychological adolescence that childhood identity begins to lose its effectiveness as a source of security that it once provided. Because of the pressure for maturation, a pressure that originates from an internal source as

well as from the external world, a new identity must be sought. Self-identity is an internal experience, the result of the interlocking of multiple aspects of living with external and internal reality. Important components of self-identity are the ego ideal and the superego. Together they assure a certain degree of self-predictability based upon the individual's own values. While the ego ideal and superego are typically so interrelated it is often difficult to tell them apart; during adolescence the demarcation between the two is frequently apparent and the source of confusion for the adolescent (as well as others).

The theoretical differentiation used in this discussion is based on Piers's delineation of the difference between shame and guilt. Shame is related to a failure to live up to the individual's self-concept of what he wishes to be; guilt is the response to failure to live up to what is expected by those meaningful in interpersonal relationships, primarily the parents and the established social mores. The ego ideal defines the healthily narcissistic value system that assures self-appreciation. It is the formulation of a gestalt that indicates, "This is the kind of me *I* can love." The superego, when artificially separated from this, defines, "This is the kind of person who will not be punished, but will be loved by others." The reason for the typical interrelatedness of these two in a psychologically healthy individual is apparent. There is not much love for the self if punishment, including loss of love, by others is not avoided.

During adolescence the childhood ego ideal, which was based upon being a self-loving and lovable child, is partly abandoned. The lovable self must attain an identity as an adult, not only in a social, economic, and parental role, but as an integrated internal self-concept. The adolescent strives to find an ego ideal that will, as it becomes crystallized, result in respect for the self as an adult, not as a child.

During his latency the adolescent achieved a meaningful relationship with his peer group, he learned the rules of the game for living in the world of his peers; his earlier ego ideal had become enriched by including the requirement of being a good player in that game. His self-image thus had incorporated social standards as well as the standards of his family. Discarding this social ego ideal and alienating himself from his peer group threatens a basic component of what he seeks, a new ego ideal. As a result he is ashamed if he does not protest a parental demand as his peer group does, or claims they do. He is ashamed if he dresses differently from his companions and if he does not join them in violating a school dress code. He probably would not mind not wearing ragged blue jeans, and even would not object to wearing a necktie to school, except that to do so would be to abandon the self-confidence that has resulted from social acceptance by that world of which he had become a part during latency.

On the other hand, often the code of his peer group violates an aspect of

a family- rooted superego. The superego that developed during childhood was primarily the result of an internalization of parentally imposed standards. As the superego takes charge, the responses become autonomous, providing guidelines not only to assure avoidance of punishment but, more importantly, to assure a continuity of the needed primary love of parental figures. If these internalized guidelines are not followed, guilt results.

Some of the values of the childhood superego relate to wise prohibitions relevant only to childhood; others relate to values applicable at all ages. It is not always an easy task for the adolescent to differentiate them. A simple example of a significant component of the childhood superego that must be modified if adulthood is to be attained is the child's internalization of the attitude that parents must be obeyed. There are cultures in which that aspect of the superego remains intact in adult life. On the whole, however, in our current culture the normal adult's attitude is based upon the concept of self-determination.

To attain mature status the individual must learn to differentiate between those superego standards that are universally applicable to society and those that are a remnant of a childhood role. While parents are often aware of the necessity for this shift and give verbal sanction to the change, the childhood superego has become so much a part of the individual that its origin in parental standards has become vague. While the parents' assurance

that modifications are correct, because what applied in childhood no longer applies, does aid the adolescent in his attempt to attain a more mature superego, it does not automatically bring about the shift.

Helen, a college student, who was reared in an academically oriented family, had (except for one episode of serious illness), an unbroken record of class attendance through high school. This record was highly praised by the parents; any deflection from it because of a cold or a headache (she had migraines) would have been seriously criticized. She became a student at a college dedicated to independent study, where class attendance was determined by the student's own desire to learn what the professor was discussing at the time. In spite of her parents' enthusiasm for this educational approach, she could not fail to attend daily every class in which she was enrolled; she indicated she would feel too guilty if she didn't. As a result she could not find the time to pursue her independent study. Finally she solved the problem by transferring to a college that required class attendance and repressed any student initiative!

The typical adolescent, sometimes overtly, sometimes covertly, handles the conflict between his childhood superego and the pressure to modify it to comply with his image of an adult value system by rebelling, sometimes seriously, more typically in a token fashion, against his own superego. In doing so he frequently first projects that superego, using its original source as

the object against which to rebel—namely, his parents or those he sees as rigid and authoritative people. (This may at times be a realistic technique!) He may reveal some behavior that he has tried to keep hidden from his parents, insisting they would not let him do it if they knew. A discussion with the parents may indicate that they would not condemn the act; rather they had wondered why he was not doing it. Pointing this out to the young person may relieve him; in some instances, however, it makes him uncomfortable. He has been deprived of a token enemy, the projection onto another of an internally established but inappropriate value system that he wishes but fears to abandon.

To the adolescent, rebellion against an internalized value system is at times frightening. The superego provides security, assuring him that his behavior will not be unpredictable. As a consequence the rebellion against the superego often may be abandoned temporarily and the early standards held more rigidly than previously. At such times there is a possibility of the evolvement of a strict, crippling superego in adulthood. In the typical individual this possibility results in a reactivation of the rebellion against the earlier value system and, usually through verbalization rather than action, a flaunting of imposed standards.

Currently there may be an interesting manifestation of this. Young people, and many adults, talk about the change in sexual mores among the

young. Yet statistical studies of college students during the 1960's did not confirm this modification.'> Why does this contradiction exist? It is possible that one aspect of the contradiction represents a wish and the other represents an actuality. Maybe the mores arc not changing as much as the young people indicate they are. On the other hand, it is equally possible that the mores have changed. If so, to what extent does the acceptance of the change provide an opportunity for a wish to be expressed unconsciously through interest in the behavior of others rather than to be acted upon secretively and guiltily? Perhaps when the present generation are in their fifties we will know whether statistics or impressions were correct during this time span.

As alarming as the rebellion against the superego may appear both to adults and to the adolescent himself at times, it usually does not take a serious form. A well-structured superego developed during childhood results in the major aspects of the value system remaining intact. Those aspects that succumb to the adolescent rebellion are more typically relatively minor changes as far as social living or individual maturity is concerned. He may rebel against wearing socks to keep his feet clean, but he doesn't steal or murder!

As indicated previously, differentiation between the ego ideal and the superego is usually difficult because the two, which during childhood and

hopefully when adulthood is attained are melded and interrelated, are frequently in conflict during adolescence. A patient described his conflict succinctly in one situation. He and a group of friends planned a trip to Europe that would involve a minimal expenditure for living expenses. Each individual of the group had earned the money for the limited budget they projected. His parents, not wishing him to be stranded in a foreign country, gave him traveler's checks to be used in an emergency. At first he was happy to have the extra security, but then he experienced an overwhelming sense of shame. His friends were acting as independent, mature individuals; he was secretly more secure because, under a veneer of independence, he was a child being taken care of by his parents. He became so uncomfortable under this burden that he returned the traveler's checks to his parents. When the parents' attempt to persuade and cajole him to accept the checks failed, they became angry, pointing out they would worry about him and their summer would be ruined. This created intolerable guilt in him; he almost abandoned the trip because of the discomfort resulting from the conflict between his ego ideal and his superego. Fortunately he solved the conflict by telling his friends about his "neurotic parents," and by plotting with his friends for a splurge with the traveler's checks during their last days in Europe.

Adults find it difficult to understand certain aspects of the adolescent's struggle to define an adult ego ideal and superego for himself; therefore, they are often unable to help him wisely in his psychological clumsiness. Part of

what the adolescent seeks are an ego ideal and superego that will incorporate an occupational role he respects for himself and the training for and achievement of a work identity that will, through acceptance of obligations, achieve approval, not punishment, and a place in society for him. High school and college educators commonly indicate to parents that if their son or daughter are planning to go to college, the parents should not be concerned if the young person frequently shifts his or her vocational goals, or appears to have none; he or she will find that in college. Regardless of the practical aspects of ability, a beginning college student who has not mapped out his occupational future is still confused about one aspect of his adult ego ideal and superego; he has not as yet determined who, vocationally and as a part of a social structure, he wants to become.

Regardless of the healthy effectiveness of his childhood ego ideal and superego, the adolescent, in order to reach relatively healthy adulthood, must abandon those values that were appropriate only during childhood, or that were necessary in his situation as a child, and selectively retain those of value for all ages. While his selection is facilitated through the wise, not rigid, counseling of others, the selection must be *his* if he is to experience a true self-identity, not just one that is an image in a mirror, the image of someone else.

Adolescence as Rebirth

The ego ideal and superego do not develop independent of other steps in psychological growth. They are both the result of, and the stimulus for, that growth. This suggests another facet to explore in regard to the adolescent period. Bios has referred to adolescence as a time of the second individuation process, which for brevity could be termed "rebirth." This conceptualization would seem the most broadly descriptive term of adolescent psychology. In seeking a new identity, the individual recapitulates the process of development that resulted in the integration achieved in his childhood. Although it would be simple if the repetition compulsion described by Freud were not a part of human psychology, clinical evidence suggests that at least the human species does not abandon the past to start anew, but rather repeats the old in order, if possible, to find a new answer. During adolescence the individual seeking a new identity recapitulates the phases of development that resulted in his childhood identity. In contrast, however, to the clinically typical repetition compulsion, he does so with new tools and with new goals. To the extent that he mastered any earlier phase, the recapitulation during adolescence will be more easily handled, other things being equal, than if his mastery was incomplete or dealt with by the utilization of unfortunate defenses. It is because of this tendency to relive the past, and reevaluate it in terms of the future, that adolescence cannot be understood as either isolated from the past or as the beginning of attainment of the goals for the future. It is a rebirth in which neither the first birth can be ignored nor the future of the

reborn person be assumed to be alien to the initial growth process.

Body Image in Adolescence

According to the concepts of this article, psychological adolescence typically begins at the time of the spurt in growth and the body changes associated with prepuberty and puberty. This physical change results in the young adolescent experiencing an unfamiliarity with himself. We know a piece of glass is a mirror because when we look into it we see a body that is ours. Imagine what the experience of seeing his reflection would be for a thirteen-year-old boy, who had not seen himself in a mirror for a year, during which time he had grown several inches and his body contour had changed. Actually, in a less dramatic way, the adolescent's body, because of the typical body changes, is less familiar to him than in the past. As one boy who had grown quite rapidly half-humorously commented, "I wonder if I am farsighted; my feet are so far away when I stand up, but I can still see them."

Because children and adolescents have been encouraged to engage in physical activities that require good body coordination, the body awkwardness of 50 years ago is not as universally observed among the adolescents of today; during the period of rapid growth the young person is sufficiently involved in physical activity to coordinate more effectively on the whole. If an adolescent does show the physical awkwardness that used to be

considered so typical of adolescence, and if his history indicates that prior to his spurt of growth he appeared well coordinated, it is possible to observe how an adolescent actually does, as a result of physical changes, feel unfamiliar with his body. His self-identity through body familiarity is undermined.

If adolescence is conceptualized as a rebirth, this manifestation resembles what occurred in the past as the infant began to become aware of his body. The infant lacked the development that enabled him to handle his body as he would later. In contrast to the adolescent, the infant did not know from where he came; he could not recall his fetal state before he had hands, arms, and legs. The adolescent, discovering a new encasement of himself, does know his physical past; he is often proud of the changes he sees in himself. But he does not necessarily feel at home in this new encasement.

As a consequence of the changes that have occurred, an adolescent is very conscious of his body, both its beauty and its malfunctioning. He is aware of body sensations that are often alarming to him because he doesn't understand them; he is fearful that abnormalities are developing that will make him an inadequate adult in the framework of his own sex. An example of this is the temporary development of a deposit of adipose tissue in the breasts of a boy, particularly if he is obese; he fears his body will be effeminate. The girl may be concerned because her breasts are not developing

rapidly enough, and she fears she will have a masculine body while she is striving to see her body as indicative of her femininity. These responses to confusing patterns of physical development are significant in evaluating the "normal" adolescent. Thus, the boy who has a feminine identification may value his breast development; the girl may value her "boyish" figure because it denies her biological femininity. But concern about body development does not always indicate pathology.

Awareness of the possibility that his body encasement might not be perfect should make the adolescent very careful of his body. Although he will be careful at times, at other times he will act alarmingly to the contrary. He then may manifest many of the characteristics of the oral phase of development. When feeling lost in his interpersonal relationships and in his world, he may revert to the same comfort source that he found gratifying during infancy. He may overeat in spite of gaining too much weight, or he may eat foods that he knows the doctors believe cause acne. Food represents to him comforting that in infancy was provided by others but that he can now provide for himself.

The problem of differentiating between a normal conflict, for which a temporary solution is sought, and a serious conflict, which the adolescent cannot handle, becomes apparent in the case of adolescent eating patterns. As indicated above, if transiently insecure he may handle his longing for the

support found during infancy by eating. He may also be obese or deny the doctor's recommendations about acne because being unattractive is protection against the gratification, particularly sexual, that he fears he would be tempted to achieve were he not physically unattractive.

Kate illustrated rather dramatically the interlocking between a transient and a deeper, more sustained conflict. With a lifelong history of a tendency toward overweight, she became a compulsive eater and rapidly gained weight during early adolescence. She was quite insecure during this period, an insecurity that appeared related to her confusion about her goals and to parental criticism of the lack of future plans. A rather sudden spurt in academic achievement resulted in increased self-confidence and adherence to a reducing diet. The latter was very effective, and in about two months she became an attractive, feminine adolescent. Then her compulsive eating patterns returned and with them her obesity. Her self-confidence appeared to remain intact. It became clear, however, that her compulsive eating returned at the time boys in her class changed their response to her. Previously she had been an asexual friend to them; after she lost weight they sought her as a "girl friend." She finally recognized that she had been frightened by this change in the boys' attitude. Her sexual conflict, which had aspects of a conflict deeper than her original insecurity, only then became clear.

Dependency during Adolescence

This reliving of early infancy becomes manifest in other broader psychological responses. Although it is often stressed that adolescence is a time of striving for independence—which it certainly is—the great dependency needs of the adolescent may be overlooked. As he attempts to become more independent and strives to find his own self in a new form, he may overextend himself, or fear that he has.

This creates anxiety; he then appears to regress to a dependent state characteristic of a period when he really was helpless. He loses all confidence in his own ability to make decisions and seeks advice from parents or parent surrogates. He usually does not seek advice on deep philosophical questions, which adults would probably willingly give at great length. The advice frequently sought is whether to ask a certain girl for a date, what courses to take the next semester or, by the girl, what dress to wear, or whether her lipstick is really a good color for her. The normal adolescent, when he seeks such advice, may become angry with the advice that is given. From the standpoint of adolescent psychology this is easy to understand. If the advice is asked because of anxiety, the fact that advice is given relieves some of the anxiety; then a new discontent arises. The adolescent does not want to be dependent upon parents or even parent surrogates; he wants to have respect for himself as an individual. The only way he can achieve that, in his mind, is to refuse the advice given. He therefore says the advice is stupid and does the opposite. Fortunately, if the earlier child-parent relationship was positively

meaningful, the adolescent is more apt to confuse his parents by seeking advice as if he wanted it primarily to do the opposite only in regard to relatively minor, token aspects of his living; the color of lipstick is really not that important.

There is another factor in his seeking advice on minor events in his life. If the advice is given it assures him that in times of real stress he can still depend on his parents for guidance, even if he is attempting to be independent. The mature adult does not wish to be independent to the extent that he will not utilize the expertise of others. It is not surprising then that the adolescent, while striving for his naive concept of independence is frightened at times and seeks in a real or token way people to whom he can turn who are more experienced and who will offer a helping hand if it is needed.

In areas related to long-time, meaningful goals, the adolescent is more willing to listen to the adult because he does want external help in sorting out his confusion; the long-time goals are aspects of his life that he is mulling over but about which he does not have to make an immediate decision as he would if he had to decide whether to take a girl on a certain date. On important issues the normal adolescent listens and often stores away what he hears to think it over in his own secret way, even though on the surface he may seem to resent the advice and imply that he will do the opposite. Adults who say to the adolescent asking for advice, "Don't ask me because you will do as you

please anyway," may lock a door that should be left open, irrespective of whether the adolescent walks through it at that point.

Redefining of Self-Object during Adolescence

Another manifestation of adolescence as a rebirth is the negativism observable in many psychologically healthy adolescents. Just as it does with a two year old, negativism plays a significant role in the maturation of the adolescent. The two year old, as he becomes aware of the strength inherent in being an individual instead of a compliant extension of another, gains increasing confidence in his separateness by saying "no." "Yes" is as if he were putty; "no" indicates a strength of a solid form. The infant, as lie becomes aware of his separateness from others, assures himself of a new-found identity by being negativistic. Childrearing practices of any culture lead to a gradual remission of negativism paralleling a growing assurance of self-identity within socially imposed and reality limitations.

The young adolescent, since he senses that the identity he established as a child is not the adult identity that he now is seeking, utilizes again the mechanisms that first established his own self-concept. He also, in a different form, is negativistic. If society decreed that all men should have long hair, it could be anticipated that many long-haired adolescent boys of today would shear off their locks. When miniskirts became acceptable high school attire,

the maxi skirt became the vogue. It is the new style accepted by the extremists but questioned by the greater majority of adults that often, if the protest of the latter is strong enough, provides an immovable object against which to assert the valued, irresistible force of negativism, becoming the adolescent *cause celebre.* It is the way to be "different," not different from the peer group, but different in the eyes of those who established the childhood code the adolescent had accepted in the past.

The psychologically healthy adolescent does not intentionally carry his negativism beyond a point of no return unless he is driven to do so by the counternegativism of adults. Unfortunately the point of no return cannot always be delineated and can at times be evaluated only by a longitudinal study. Will an intelligent boy, who is negativistic in his rejection of education beyond high school and apparently deaf to all advice concerning the advantages of further education, ultimately invest himself in further education after he has effectively established his own self-realized identity, or will he cling to the identity his negativism provided him with? The answer may become apparent retrospectively after his adult configuration has become solidified. Fortunately most psychologically healthy adolescents do not go beyond the point of no return.

The Sexual Drive in Adolescence

With the advent of adolescence the sexual drive becomes intensified, partly because of the increased secretions of the reproductive glands. Less sexual confusion exists in simpler societies in which the increased drive can, within the framework of the mores of the social structure, find more readily a permitted pathway of expression with the opposite sex. For many reasons Western culture does not sanction such a pathway; instead, it complicates the early discharge of sexual tensions by fostering the ideal that mature sexuality represents a fusion of a biological urge and the emotional desire to love and be loved.

In Western civilization being loved and loving, at least consciously asexually, are freely expressed, optimal emotional experiences during childhood. Many theories of psychological growth patterns consider the preadolescent experience with love as the roots from which the ultimate heterosexual fusion of sexuality and love grows. The masturbatory fantasies of the child prior to adolescence indicate that the fusion, in an immature form, begins prior to the onset of adolescence. The intensified sexual feelings of the young adolescent are not yet directed solely toward an heterosexual goal. They readily become a part of any emotionally invested experience. They contribute to the intensity with which the young person responds to both pleasure and disappointment. These modes of discharge are often experienced without conflict.

In a desirable family milieu the child's primary love objects are his parents; the clearest pathway for expression of fused sexual response and love is thus the familiar one of love for the parents. Because of the increased intensity of sexual feelings, this leads to a reactivation of the oedipal conflict. The incest taboo became well imbedded in the psychological format of the individual as he struggled for a solution to the oedipal conflict in childhood. The prohibition is reinforced during adolescence because in addition to the incestuous implication, love for the parent represents remaining immature and a child in his own eyes and those of his parents. He thus must deny and repress the reactivated oedipal wish. He frequently denies it in his emphatic refusal to tolerate physical contact or any suggestion of seductive behavior by the parent of the opposite sex. Repression of the wish is not as easily achieved. Dreams of the adolescent often have a poorly disguised or undisguised incestuous nature. To add to the confusion, the most apparently rejecting son or daughter will have moments of being pleasantly and harmlessly seductive with the parent of the opposite sex.

Frequently the adolescent attempts to solve the oedipal conflict by a denial of affection for the parent of the opposite sex, and he experiences an intensification of positive feelings for the parent of the same sex. This offers a dual conflict again. To relate in this fashion to a parent of the same sex again represents a threat of returning to childhood. It also frightens the adolescent because he recognizes the possible implications of a homosexual orientation.

Consequently he denies, or attempts to repress, his affection for the parent of the same sex and resents any implication of a strong emotional tie. The adolescent vacillates between this and a "man-to-man" or a "woman-to-woman" relationship with the parent of the same sex.

Parents contribute to the intensity of the reactivated oedipal conflict. The mother finds her son in his good moments a delightful male, and she utilizes her flirtatious manners that may have become ineffectual with her long-time mate. She avoids the conflict inherent in such a response to her son by being "motherly." When, for example, she kisses him and he protests, her answer is, "Why won't you let *your mother* kiss you?" He probably doesn't know why, but he does know that he is uncomfortable. A father likewise, when the son is in a good mood in which he feels free to express his affection in a manner that he cannot express it to his male friends, finds with him a gratifying relationship. The reverse situation exists with a girl; her father finds her budding femininity stimulating, and he, under the guise of being "after all her father," responds warmly to her. She, if needing to deny her affection for her father, is often quite resistant to his overtures. When she is not fighting any expression of her affection for her mother, she again provides the mother with a closeness that the mother does not know with friends.

These responses by parents, while increasing the young person's conflicts, are not, unless excessive because of the neurotic need of the parents

or of the young person, an unfortunate response. A boy gains confidence in his own masculine attractiveness as a result of his mother's response. He also gains strength from his closeness with his father if the struggle for self-identity becomes too overpowering and external support is needed. The girl likewise gains confidence in her femininity from her father's response. At the same time her closeness to her mother, when it is needed, provides her with an opportunity to discuss her own femininity and to model herself after a loved woman. Just as the oedipal conflict is an essential part of maturation in childhood, it is an essential part of the maturational phase of adolescence. If parents are not available to play this role, appear too threatening, or are unwilling, other surrogates are frequently sought, as indicated in the ambivalent relationship with a basically loved teacher, or other adult, expressed by the "crush."

During the adolescent phase many solutions may be tried to resolve the oedipal tie, solutions that if they were to become a permanent part of the adult character structure would have unfortunate repercussions. For example, a boy, instead of turning toward his mother, may transiently seek a girl who will mother him; he may seek a girl who represents only a sexual object; he may deny any interest in any girl; or he may choose a girl who does not have a psychologically feminine orientation. He may turn to an older man or to some male peer whom he can love as he fears to love his father. He may renounce his masculinity, rejecting any identification with his father or any

masculine figure. These intense, frequently ambivalent relationships are often brief. While this brevity may be evaluated by the adult world as evidence of fickleness and a lack of investment in any relationship, it may be indicative of a wise rejection of possible solutions to the oedipal conflict.

One of the disquieting manifestations of this attempt to solve the oedipal conflict—disquieting to both the young person and to adults—is the implication that adolescent sexual attachment toward a person of the same sex is the harbinger of an ultimate homosexual adult life pattern. In some this type of behavior may represent a fixation at a homosexual level. In a psychologically normal adolescent this is not true; it may, however, become a fixation at an adolescent homosexual stage if unwisely handled. Many adolescents who at times appear to be homosexual are in reality trying to find a substitute relationship with someone who will serve in a surrogate parental role as the struggle to be free of the child-parent relationship is being waged in spite of the anxiety such a separation arouses. As mentioned above, because the goal of sexual feelings is not yet crystallized, such feelings may become a direct, unsublimated component of any internally meaningful experience.

While the reintensification of the oedipal conflict is an important part of the confusion of the adolescent as he deals with the increased intensity of his sexual aims, it is by no means the sole source of sexual conflict. In most

cultures he faces many other major problems, as he tries to attain mature heterosexuality, which is both biological and social. Particularly if his relationship with a parent figure (during childhood) has led to an identification with a mature person of his own sex, he sees adulthood as attained sexually by emulating the person of the same sex. In the past this adult had appeared to be a giant, he himself a pygmy. As a consequence his identification with the older person has not assured him that he is the same, particularly in sexual potential. He wishes to attain sameness; he is not confident he can.

The adolescent feels unsure of his sexual competence. Because he has doubts about his own sexual adequacy, he fears it will be seen by others; because of his tie to a person of the same sex he worries about homosexuality. To deny these concerns, he may talk or act out a genital sexual pattern compatible with heterosexuality. If he only talks it, he often is masking a deep fear that he can't act it out. If he acts out a pseudoheterosexual role, he either finds it unsatisfactory or is vaguely aware that the sexual act itself is a mutual masturbatory experience, far short of what he believed a true, mature heterosexual experience would be. The latter is particularly disturbing to the young adolescent girl, for she is often frigid. She interprets this as evidence of her failure in her feminine sexual identity. The fact that the reproductive glands do not reach full maturity with the increased functioning at puberty probably contributes to some adolescent confusion. There has not been

sufficient study of this to state it as more than an hypothesis, but it may be that part of the difficulty in fulfilling the sexual goals of the young adolescent is related to this immaturity.

In today's culture sexual fulfillment is not evaluated only by the capacity for genital discharge of sexual tension with anyone of the opposite sex. It is considered to be attained when love for the sexual partner and sexual discharge are one. Often the love an adolescent experiences for another person of the opposite sex is an expression of a need of the young girl or boy that is not readily melded with sexuality. Possibly such melding cannot occur until the sexual glands have attained a stable maturity, and emotional needs and responses have also attained relative maturity.

Social Meanings during Adolescence

Fortunately for parents, as well as for the adolescent, the normal adolescent has days or months in which he is reliving the latency period. He is interested in his school work, but now he orients it to the reality of his future, not just to the present. He works out in fantasy many possible roles that he can play in the social and economic structure when he becomes an adult. He is interested in sports, either as a participant or as an observer, and formalizes into a social philosophy for the future the standards of fair play and sportsmanship that he learned during his latency. Temporarily the mountain

toward maturity that he has been struggling to climb has become a restful plateau, both for himself and for his parents.

There is one exception, however, to this plateau concept. During this period he often translates his philosophy into thinking about social issues, the status of minority groups or of others less fortunate than himself, political formulations or international relations. These ideas have intense affective meaning, but inevitably reflect a limited grasp of all the reality implications. His protest becomes verbal, and he may join with those who with similar idealistic goals verbalize their feelings, often expressing hostility toward those whom they consider barriers to the fulfillment of their goals, for example, the Establishment. The reliving and reevaluation of latency temporarily becomes a source of concern to others and may lead the young adolescent into activities that are basically incompatible with the philosophy he is expressing.

This behavior has many components. The social formulations of latency provide a way to escape complete self-absorption; the social structure, not the self, must find new rules by which to live. Lack of life experience leads often to naive, but sincere concepts. At the same time, however, it is not only inexperience and the resultant naiveté that energizes the drive toward these social goals. The drive may be intensified by: the wish to find an area of adequacy; the need to find a securely dependent relationship in a group that

provides a familylike unity that is obviously not the primary family; the need to rebel against the symbol of a childhood relationship with his family (at present the Establishment) in order to establish a confident respect for the self; or a wish to discharge sexual tension through love for a cause and for individuals who are abstractions and thus do not threaten intimacy.

"Regression" during Adolescence

The recapitulation during adolescence of childhood patterns of adaption and defense, and the firm establishment of defenses and adaption against ego-alien impulses, is described by many as regression in response to the intensification of inherent needs and drives. This concept would imply a temporary ego failure. In some cases even in relatively normal adolescents this is probably a valid assumption. An example of such regression would be when overeating to the extent of causing obesity occurs because food represents love (as experienced in infancy). In the normal adolescent, however, the way in which childhood is relived is not characteristic of the past, but rather is an attempt to correct the child-oriented solutions of psychological conflicts, thereby attaining, hopefully, an adult identity.

In many ways it parallels the latter part of a successful psychoanalysis; the patient, after regressing and coming to recognize the infantile manner in which problems have been handled, reconstitutes himself to attain in an adult

fashion those goals that were sought in childhood in a childlike way. The normal adolescent does not have to uncover the unconscious use of childhood tools; he is experimenting with new tools that may more adequately serve his needs. Many of the former tools prove of value with or without some modification; even though at times he casts them aside, he ultimately uses them again. Other and new tools appear at times to be the only answer to reconstituting himself as an adult. Gradually he recognizes the importance of multiple and functionally interrelated approaches. As a consequence he interlaces his multiple needs, wishes, and drives, binding them together with adaptive and defense mechanisms that finally represent an identity that is himself as an adult.

Resolution of Adolescence

This process occurs throughout adolescence, but during the early phase there is a chaotic pattern that gradually becomes a discernible design in later adolescence. He achieves that ultimate design by finding, not always optimally, a solution to each recapitulated phase of early development.

He becomes at home in his new body and with his new physiology. This is facilitated by the completion of the physical and biological growth that has been initiated by prepuberty and puberty. He has a body image of himself that represents his external self-concept.

He learns by experimentation, evaluation, and from the behavior of others the wise limits of independence. He also, as he feels safer in his achievement of wise independence, finds that to be dependent on others is not necessarily to be a child. Dependence is childish only when it is sought as a child would. He becomes aware or unconsciously accepts that society is based upon the interdependence of its members—an adult form of dependency in the human species.

As he becomes increasingly familiar with, and secure in, his nonchild self-identity, he does not have to protest so emphatically that he is a person in his own right. What was negativism earlier becomes a capacity to think rationally about those issues that previously aroused his negativism. Hopefully he does not completely abandon his earlier naive attitudes, but rather exposes them to a rational evaluation that enables him to see their weaknesses and potentials, and to outline a course toward fulfillment of their positive potentials.

He resolves the reactivated oedipal conflict by turning to a member of the opposite sex for sexual gratification, a nonincestuous object acceptable to himself. His sexual feelings, lacking goal direction in early adolescence, has become goal oriented; he has attained a mature heterosexual level of sexual maturation. With this forward step he can experience his nonsexual love for his parents without anxiety, accepting them and hopefully being accepted by

them as an adult with virtues and shortcomings. A tie to his parents persists, well-established through the years of childhood. The tie does not bind, it only enriches. It contributes to the capacity of the young adult to be a parent.

Experience and biological maturation brings confidence in his (or her) sexual identity as a male (or female). A sense of sexual adequacy relieves the anxiety experienced earlier and frees the individual to enjoy that adequacy. At the same time there is a relief from the strain of multiple sexual goals, and gratification in meaningful relationships such as friendships that have now become asexual is found.

Whereas previously he had vacillated, he incorporates defined role patterns for himself with the development of familiarity and the acceptance of his own identity. He clarifies his role in his family of the past and, if married, his new family; he finds secure employment; and he accepts responsibilities in accordance with the society of which, as he now accepts, he is an integral part. He has become an adult. Later he may modify or change the roles, but he will not do so impulsively or confusedly, but only after careful exploration of the multiple facets of his familiar role and the new one by which he is tempted.

Obviously the preceding recapitulation of the resolution of adolescence formulates a theoretical termination that in reality is possibly never

completely achieved by any individual. One of the frequent unfortunate consequences of failure to achieve an adequate resolution of adolescence is the loss of the emotional sensitivity and responsiveness of adolescence. As their naiveté is confronted with the negating aspects of reality, too many resolve the conflict by repressing the sensitivity and responsiveness rather than incorporating it into an approach to reality. Unfortunately this is not usually considered as pathology, but rather as evidence of growing up. To the extent that repression instead of maturation of this aspect of adolescence occurs, to that extent any cultural growth is retarded. That sensitivity and responsiveness, if it matures, results in the individual's capacity to care for, to be involved in, and to offer wise participation and leadership in areas beyond his immediate interpersonal relationships. That widened capacity protects society from his use of any unusual creativeness he may have solely egocentrically; instead, the creativeness will also be beneficial to those who are represented to him only through the abstractions of "society."

To summarize, during infancy and early childhood the individual struggles with the basic maturational conflicts that appear to be characteristic of the psychological development of at least the human species. With the attainment of adolescence these conflicts are reactivated, and the individual is "reborn" to face the psychological task of formulating an adult identity. What he ultimately formulates, or fails to formulate, will be significantly affected by his infancy and early childhood experiences, but not necessarily irrevocably

determined by them. To the extent childhood conflicts are resolved constructively, to that extent adolescent conflicts will have a greater possibility of a constructive resolution. Irrespective of the childhood past, however, adolescence is a phase of rebirth that, if relatively achieved, brings forth an adult.

The preceding article is a description of the manifest behavior of the normal adolescent. To probe deeper into the psychodynamics of the adolescent phase, the following publications are suggested:

Blos, P., *On Adolescence,* Free Press, New York, 1962.

Chapter 19

Youth and Its Ideology

Kenneth Keniston

Most discussions of the life cycle assume a certain fixity of life stages.[1] Psychiatrists, social scientists, and laymen in the Western world take for granted that life can be divided into a definite series of "stages," beginning with early infancy, continuing with two or three further stages during the preschool years, followed by a stage of "childhood" that extends until puberty, then by adolescence, early adulthood, and so on until old age and death. These are, after all, the stages of life that are acknowledged, sanctioned, and institutionalized in modern industrial societies.

The Psychohistorical Contingency of Life Stages

It has gone relatively unnoticed until recently that other societies and other historical eras segment the life cycle in different ways. As Erikson notes in his discussion of Indian concepts of the life cycle, there are indeed parallels between his own theory of human development and the traditional wisdom of

Indian culture. But equally impressive are the differences—the "failures" of Indian tradition to recognize developmental milestones that are considered critical in Western society, the Indian emphasis on developmental issues that pass virtually without notice in the West. Similarly Eisenstadt, in his discussion of age-grading in the life cycle, underlines the enormous variability between societies in the extent to which they place children in narrowly defined age-grades.

Historians, too, have recently pointed out that even in medieval European societies such apparently universal stages of life as childhood and adolescence were not recognized. For example, Aries, in his study of medieval concepts of the life cycle, shows that nothing like the modern notion of childhood existed. Instead, the medieval child at birth entered a stage of life called infancy, which lasted six or more years. After infancy he was simply considered a small adult, expected to dress and act like what we would today consider a grown-up. Obviously, medieval Western society must have recognized that those whom we call children were in some ways different from those whom we call adolescents and young adults. But this recognition was nowhere institutionalized or sanctioned. For example, insofar as schools existed at all, they were graded by ability, not age: the same medieval classroom might contain within it students from eight to 45, grouped on the basis of their mastery of the classical curriculum. Aries argues that a "sentimental" view of childhood only began to emerge in the seventeenth and

eighteenth centuries. In this new view children were thought to possess an "innocence" that required protection from the adult world; age- grading increasingly dominated the widening network of schools; and a stage of life corresponding to what we call "childhood" was gradually recognized and sanctioned.

Aries's intent is largely to describe rather than to explain. But it is noteworthy that the recognition and sanctioning of childhood as a stage of life overlaps with social, technological, and economic changes that drastically altered medieval life. Specifically, childhood emerged and flourished alongside mercantile capitalism, which produced an increasingly large and prosperous bourgeoisie that could exempt its children from the work previously necessary for family economic survival. A mercantile society also required of an ever growing minority of the young a new fluency with written language and numbers that rarely could be taught at home. For the new clerks and merchants of the seventeenth century, education was no longer simply a kind of training for virtue through knowledge of the classical curriculum and the Scriptures. Increasingly it became a prerequisite for social mobility, wealth, and power. Furthermore, the development of an entrepreneurial society in Europe seems to have been impelled by the psychological qualities summarized in the concept of the Protestant ethic. And it may be that the development of these qualities requires a period of "protection" from adulthood that extends well beyond the medieval period of

infancy. Clearly, then, the emergence of a concept of childhood is correlated with changes in the social and economic structure of Western Europe, which, in turn, transformed the matrix of opportunities and expectations within which children grew up.

If the widespread acceptance of childhood as a separate stage of life is no more than three centuries old in Western societies, the concept of adolescence is even more recent. Freud, writing at the turn of the century, spoke of the "transformations of puberty," but did not discuss adolescence as a separate stage. Indeed, before the twentieth century it is hard to find references to a stage of life like our contemporary adolescence. John and Virginia Demos, reviewing nineteenth-century writings on childrearing and the family, note the virtual absence of mention of anything like modern adolescence until the latter part of the century. And even then those whom we would call adolescents were often discussed as a new problem, as what one writer called the "dangerous classes" who made up the street gangs that terrorized many nineteenth-century American cities. It was not until the twentieth century, and in large part because of the work of G. Stanley Hall, that adolescence was finally recognized, sanctioned, and culturally approved as a separate stage of life.

Once again the discovery of a "new" stage of life corresponded with major social and economic changes. Industrialization in a half a dozen nations

began to transform the social, economic, and familial structures of those societies. The old working family, where parents and children labored side by side in fields and factories, gradually began to disappear. Urbanism increasingly supplanted an agrarian way of life. The growing productivity of industrialized societies made it possible to "excuse" ever larger numbers of postpubescent men and women from the requirements of work. In addition, an industrial society required far more than rudimentary education from any young man or woman who aspired to status, respect, or wealth. Increasingly society demanded higher level skills that could rarely be taught at home, but that became the special province of the secondary schools that opened by the tens of thousands throughout America in the nineteenth and early twentieth centuries. In all these ways the "discovery" of adolescence corresponded with major social and economic changes that drastically affected the lives of children as they grew up.

The "discovery" of childhood and adolescence in Western societies during the last three or four centuries suggests that the segmentation of the life cycle is not a psychological or cultural constant, and that the way life stages are distinguished and defined is intimately related both to the social, economic, and technological conditions of a society and to the actual environment in which children grow up. To be sure, this correspondence between definitions of the life cycle, socioeconomic context, and the actual experiences of growing individuals is far from perfect. But the "discovery" of

childhood and adolescence at times of major socioeconomic change suggests that concepts of life stages tend to correspond with, reflect, and sanction actual changes in the modal experience of young people as they grow up in any given society and historical era.

If these surmises be correct, they have far- reaching implications for the understanding of human development. We have tended to assume that the development of all men and women is in some fundamental respect similar to that of those middle-class, relatively prosperous, and advantaged young men and women who constitute the source material for most contemporary theories of development. We have seen the life cycle as a kind of escalator, onto which the child steps at birth and up which he continues willy-nilly until he has passed through all the stages until death. This escalator model is a tempting one, for it corresponds with what we know of physiological maturation, which, barring the grossest of insults to the organism, tends to be relatively invariant in sequence regardless of social and historical conditions. The escalator model also corresponds with the fact that every society, however it defines the life cycle, does segment life in some way: age-grading, accompanied by different expectations concerning those in each age-grade, is culturally universal.

But human development, though related to both maturation and age-grading, is identical to neither. It entails qualitative changes in psychological

functioning, presumably based upon what Anna Freud' calls the increasing "structuralization" of the personality or what Piaget calls the development of ever more complex and inclusive schemata. The escalator model does not correspond with our growing knowledge concerning the contexts, environments, or matrices that promote human development, when development is distinguished from both physiological maturation and social age-grading.

Recent research has made clear that true psychological development is anything but automatic. On the contrary, development in every area, sector, or "developmental line" that has been examined turns out to be contingent upon what have been variously called environmental nutriments, supports, confirmations, or challenges. The most vivid example of developmental arrest in the absence of environmental facilitation comes from studies of institutionalized children who, if deprived of the necessary environmental supports and challenges during the first few years, suffer severe and probably irreversible retardations. " Furthermore, the utility of developmental concepts like fixation, foreclosure, arrest, retardation, and lag indicates the frequency of failures of development that occur either because of the absence of a facilitating environment or because of the presence of obstructions to psychological growth. At every stage of life and in every area of development, therefore, psychological development must be considered problematic rather than inevitable.

The contingency of human development may help us understand the large differences in the way different societies segment and organize the life cycle. For example, in many nonliterate and subsistence societies children are routinely expected to join their parents in adult work at around the age of seven or eight. What little we know about the conditions that stimulate development in childhood suggests that such societies should have drastically different effects on the final cognitive and affective development of the typical adult, when compared with societies that insist on prolonged schooling during the same years. Literacy alone appears to have massive effects on development. For example, Bruner and his colleagues, working with nonliterate groups in Senegal, have shown that nonliterate children and adults cannot understand the question, "Why did you say that?" Bruner argues that only with literacy does there emerge a capacity to reflect upon language itself, to discuss propositions as objects of discourse.

If development is contingent, there may well be important developmental potentials that remain largely unactualized in some or most societies because these societies do not provide the needed developmental facilitations or because they place active obstructions in the way of development. Furthermore, we may discover that many definable adult "achievements" are not attained by many or most people in any given society. Such, indeed, seems to be the case. For example, the psychoanalytic concept of "genitality" refers to a psychosexual orientation that is often not realized.

Similarly Kohlberg's work on moral development (see below) has demonstrated empirically the existence of high level structures of moral reasoning that are not attained by most Americans. Hauser's" studies of noncollege-bound, working-class black and white adolescents suggest that identity foreclosure rather than development may be the rule, especially among blacks. And other recent research suggests that a near majority of adult Americans lack certain aspects of the cognitive capacity for formal operations that in Piaget's work is said to emerge around the age of puberty.

Other examples abound, but the general point is surely clear. If we consider development contingent, and view the life cycle in a developmental sense not as an escalator but as a pitted and problematic path, then it becomes more comprehensible why some societies should recognize stages that others ignore. It is, of course, possible that some societies are simply "blind" to real developmental changes that actually occur in their young. But an alternative hypothesis is also opened: developmental stages may commonly occur in some societies, but these same stages (or the developmental changes and issues that define them) may be infrequent or virtually absent in other societies. Thus, major changes in the social, economic, technological, and familial matrix within which children grow up may either encourage the foreclosure of development or stimulate development to higher levels in any of a number of sectors or developmental lines.

The existing evidence—anthropological, historical, and scientific—therefore supports the hypothesis that shifting historical definitions of the life cycle reflect not merely shifting cultural fashions but actual changes in the developmental matrix within which the typical child grows up, and, thus, real changes in the type and level of development actually experienced by typical children. It is unlikely that any stage will be recognized, approved, and sanctioned until a significant portion of the young have begun to pass through that stage. Furthermore, if we assume that developmental potentials are universal, while their actual unfolding is contingent, the variability of environments in all societies makes it likely that some rare individuals will pass through any given stage of life, even in a social context that makes entry into that stage very unlikely. Thus, once a stage is culturally recognized, we can look back in history and discover men and women who passed through it long before it was named and sanctioned. But the cultural "discovery" of a stage of life tends to coincide with a time when ever more young men and women are, in fact, entering this stage, exhibiting the visible hallmarks that accompany it, and developing—at least in certain areas—in different ways and perhaps to a greater extent than had previous generations.

From Adolescence to Youth

Today the concept of adolescence, first defined and disseminated by G. Stanley Hall, is unshakably enshrined in our view of human life. To be sure,

the precise nature of adolescence still remains controversial. Some observers believe that Hall, like most psychoanalytic observers, vastly overestimated the inevitability of turbulence, rebellion, and upheaval in this stage of life. But whatever the exact definition of adolescence, no one today doubts its existence. A stage of life that barely existed a century ago is now universally accepted as an inherent part of the human condition.

In the seven decades since Hall made adolescence a household word, American society has once again transformed itself. From the industrial era of the turn of the century, we have moved into a new era without an agreed upon name—it has been called postindustrial, technological, postmodern, the age of mass consumption, the technetronic age. And a new generation, the first born in this new era of postwar affluence, television, and the Bomb, raised in the cities and suburbs of America, socially and economically secure, is now coming to maturity. Since 1900 the average amount of education received by children has increased by more than six years. In 1900 only 6.4 per cent of young Americans completed high school, while today almost 80 per cent do, and more than half of them begin college. In 1900 there were only 238,000 college students: in 1970 there were more than seven million, with ten million projected for 1980.

These massive social transformations are today reflected in new public anxieties. The "problem of youth," "the now generation," "troubled youth,"

"student dissent" and "the youth revolt" are topics of extraordinary concern to most Americans. No longer is our anxiety focused primarily upon the teenager, upon the adolescent of Hall's day. Today we are nervous about new "dangerous classes"— those young men and women of college and graduate school age who can't seem to "settle down" the way their parents did, who refuse to consider themselves adult, and who often vehemently challenge the existing social order. In mid-1970 "campus unrest" was considered America's foremost problem.

The factors that have brought this new group into existence parallel in many ways the factors that produced adolescence: rising prosperity, the further prolongation of education, the enormously high educational demands of a postindustrial society. Behind these measurable changes lie other trends less quantitative but even more important: a rate of social change so rapid that it threatens to make obsolete all institutions, values, methodologies, and technologies within the lifetime of each generation; a technology that has created not only prosperity and longevity but power to destroy the planet through warfare or violation of nature's balance; a world of extraordinarily complex social organization, instantaneous communication, and constant revolution. The "new" young men and young women emerging today both reflect and react against these trends.

But if we search among the concepts of psychology for a word to

describe these young men and women, we find none that is adequate. Characteristically they are referred to as "late adolescents and young adults"—a phrase whose very mouth-filling awkwardness attests to its inadequacy. Those who see in youthful behavior the remnants of childhood immaturity naturally incline toward the concept of "adolescence" in describing the unsettled twenty-four-year-old, for this word makes it easier to interpret his objections to war, racism, pollution, or imperialism as "nothing but" delayed adolescent rebellion. To those who are more hopeful about today's youth, "young adulthood" seems a more flattering phrase, for it suggests that maturity, responsibility, and rationality lie behind the unease and unrest of many contemporary youths.

But in the end neither label seems fully adequate. The twenty-four-year-old seeker, political activist, or graduate student often turns out to have been through a period of adolescent rebellion ten years before, to be all too formed in his views, to have a stable sense of himself, and to be much further along in his psychological development than his fourteen- year-old high school brother. Yet he differs just as sharply from "young adults" of twenty- four whose place in society is settled, who are married and perhaps parents, and who are fully committed to an occupation. What characterizes a growing minority of postadolescents today is that they have not settled the questions whose answers once defined adulthood: questions of relationship to the existing society, questions of vocation, questions of social role and life style.

Faced with this dilemma, some writers have fallen back on the concept of "prolonged" or "stretched" adolescence—a concept that suggests that those who find it hard to settle down have failed the adolescent developmental task of abandoning narcissistic fantasies and juvenile dreams of glory. Thus, one remedy for "protracted adolescence" might be some form of therapy that would enable the young to reconcile themselves to abilities and a world that are rather less than they had hoped. Another interpretation of youthful unease blames society, not the individual, for the "prolongation of adolescence." It argues that youthful unrest springs from the unwillingness of contemporary society to allow young men and women, especially students, to exercise the adult powers of which they are biologically and intellectually capable. According to this view, the solution would be to allow young people to "enter adulthood" and do "real work in the real world" at an earlier age.

Yet neither of these interpretations seems quite to the point. For while some young men and women are indeed victims of the psychological malady of "stretched adolescence," many others are less impelled by juvenile grandiosity than by a rather accurate analysis of the perils and injustices of the world in which they live. And plunging youth into the "adult world" at an earlier age would run directly counter to the wishes of many youths, who view adulthood with all of the enthusiasm of a condemned man for the guillotine. Far from seeking the adult prerogatives of their parents, they vehemently demand a virtually indefinite prolongation of their nonadult

state.

If neither "adolescence" nor "early adulthood" quite describes the young men and women who so disturb most highly industrialized societies today, what can we call them? My answer is to propose that we are witnessing today the emergence on a mass scale of a *previously unrecognized stage of life,* a stage that intervenes between adolescence proper and adulthood. I propose to call this stage of life the stage of *youth,* assigning to this venerable but vague term a new and more specific meaning. Like Hall's adolescence, "youth" is in no absolute sense new: indeed, once having defined this stage of life, we can study its historical emergence, locating individuals and groups who have had a "youth" in the past.* But what is "new" is that this stage of life is today being entered, not by tiny minorities of unusually creative or unusually disturbed young men and women, but by millions of young people in all the nations of the world.

Like all stages youth is a stage of transition rather than of completion. In the remarks that follow I will attempt to define this emergent stage in several ways. First, I will comment on some of the major themes that dominate consciousness, development, and behavior during this stage. But human development rarely if ever proceeds on all fronts simultaneously: instead, we must think of development as consisting of a series of sectors or "developmental lines," each of which may be in or out of phase with the

others. Thus, an account of youth must include an account of the more specific transformations in feeling, behavior, and personal relationships that occur during this stage. Third, youth is of all stages of life that in which issues of ideology, built on cognitive, intellectual, and ethical development, play the most visible and central role. Fourth, youth, like all stages of life, has its own stage- specific psychopathology, just as disturbances common to other stages of life may take a specific youthful form. And finally I will try to make clear what youth is not, in order to underline what it is. What follows, then, is a preliminary sketch of the issues that seem important to understanding youth as an emergent stage of life.

Major Themes in Youth

Perhaps the central conscious issue during youth is the *tension between self and society.* In adolescence young men and women tend to accept their society's definitions of them as rebels, truants, conformists, athletes, or achievers. But in youth the relationship between socially assigned labels and the "real self" becomes more problematic and constitutes a focus of central concern. The awareness of actual or potential conflict, disparity, lack of congruence between what one is (one's identity, values, integrity) and the resources and demands of the existing society increases. The adolescent is struggling to define who he is; the youth begins to sense who he is and thus to recognize the possibility of conflict and disparity between his emerging

selfhood and his social order.

In youth *pervasive ambivalence* toward both self and society is the rule: the question of how the two can be made more congruent is often experienced as a central problem of youth. This ambivalence is not the same as definitive rejection of society, nor does it necessarily lead to political activism. For ambivalence may also entail intense self-rejection, including major efforts at self-transformation employing the methodologies of personal transformation that are culturally available in any historical era: monasticism, meditation, psychoanalysis, prayer, hallucinogenic drugs, hard work, religious conversion, introspection, and so forth. In youth, therefore, the potential and ambivalent conflicts between autonomous selfhood and social involvement, between the maintenance of personal integrity and the achievement of effectiveness in society, are fully experienced for the first time.

The effort to reconcile and accommodate these two poles involves a characteristic stance vis-a-vis both self and world, perhaps best described by the concept of the *wary probe.* For the youthful relationship to the social order consists not merely in the experimentation more characteristic of adolescence, but with more serious forays into the adult world, through which its vulnerability, strength, integrity, and possibilities are assayed. Adolescent experimentation is more concerned with self-definition than are the probes of youth, which may lead to more lasting commitments. This

testing, exacting, challenging attitude may be applied to all representatives and aspects of the existing social order, sometimes in anger and expectation of disappointment, sometimes in the urgent hope of finding honor, fidelity, and decency in society, and often in both anger and hope. With regard to the self, too, there is constant self-probing in search of strength, weakness, vulnerability, and resiliency; constant self-scrutiny designed to test the individual's capacity to withstand or use what his society would make of him, ask of him, and allow him.

Phenomenologically youth is a time of alternating *estrangement and omnipotentiality.* The estrangement of youth entails feelings of unreality, absurdity, isolation, and disconnectedness from the interpersonal, social, and phenomenological world. Such feelings are probably more intense during youth than during any other period of life. In part they spring from the actual disengagement of youth from society; in part they grow out of the psychological sense of incongruence between self and world. Much of the psychopathology of youth involves such feelings, experienced as the depersonalization of the self or the derealization of the world.

Omnipotentiality is the opposite but secretly related pole of estrangement. It is the feeling of absolute freedom, of living in a world of pure possibilities, of being able to change or achieve anything. There may be times when complete self-transformation seems possible, when the self is

experienced as putty in one's own hands. At other times, or for other youths, it is the nonself that becomes totally malleable; then one feels capable of totally transforming another's life, or of creating a new society with no roots whatsoever in the mire of the past. Omnipotentiality and estrangement are obviously related: the same sense of freedom and possibility that may come from casting off old inhibitions, values, and constraints may also lead directly to a feeling of absurdity, disconnectedness, and estrangement.

Another characteristic of youth is the *refusal of socialization* and acculturation. In keeping with the intense and wary probing of youth, the individual characteristically begins to become aware of the deep effects upon his personality of his society and his culture. At times he may attempt to break out of his prescribed roles, out of his culture, out of history, and even out of his own skin. Youth is a time when earlier socialization and acculturation are self- critically analyzed, and when massive efforts may be made to uproot the now alien traces of historicity, social membership, and culture. Needless to say, these efforts are invariably accomplished within a social, cultural, and historical context, using historically available methods. Youth's relationship to history is therefore paradoxical. Although it may try to reject history altogether, youth does so in a way defined by its historical era, and these rejections may even come to define that era.

In youth we also observe the emergence of *youth-specific identities* and

roles. These contrast both with the more ephemeral enthusiasms of the adolescent and with the more established commitments of the adult. They may last for months, years, or a decade, and they inspire deep commitment in those who adopt them. Yet they are inherently temporary and specific to youth: today's youthful hippies, radicals, communards, and seekers often recognize full well that, however reluctantly, they will eventually become older and that aging itself will change their status. Some such youth-specific identities may provide the foundation for later commitments; but others must be viewed in retrospect as experiments that failed or as probes of the existing society that achieved their purpose, which was to permit the individual to move on in other directions.

Another special issue during youth is the enormous value placed upon change, transformation, and *movement,* and the consequent abhorrence of *stasis.* To change, to stay on the road, to retain a sense of inner development or outer momentum is essential to many youths' sense of active vitality. The psychological problems of youth are experienced as most overwhelming when they seem to block change: thus, youth grows panicky when confronted with the feeling of "getting nowhere," of "being stuck in a rut," of "not moving."

At times the focus of change may be upon the self, and the goal is then to be moved. Thus, during youth we see the most strenuous, self-conscious, and

even frenzied efforts at self-transformation, using whatever religious, cultural, therapeutic, or chemical means are available. At other times the goal may be to create movement in the outer world, to move others: then we may see efforts at social and political change that in other stages of life rarely possess the same single-minded determination. On other occasions the goal is to move through the world, and we witness a frantic geographic restlessness, wild swings of upward or downward social mobility, or a compelling psychological need to identify with the highest and the lowest, the most distant and apparently alien.

The need for movement and terror of stasis often are a part of a heightened *valuation of development* itself, however development may be defined by the individual and his culture. In all stages of life, of course, all individuals often wish to change in specific ways: to become wittier, more attractive, more sociable, or wealthier. But in youth specific changes are often subsumed in the devotion to change itself—to "keep putting myself through the changes," "not to bail out," "to keep moving." This valuation of change need not be fully conscious. Indeed, it often surfaces only in its inverse form, as the panic or depression that accompanies a sense of "being caught in a rut," "not being able to change." But for other youths change becomes a conscious goal in itself, and elaborate ideologies of the techniques of transformation and the *telos* of human life may be developed.

In youth, as in all other stages of life, *the fear of death* takes a special form. For the infant to be deprived of maternal support, responsiveness, and care is not to exist; for the four-year-old nonbeing means loss of body intactness (dismemberment, mutilation, castration); for the adolescent to cease to be is to fall apart, to fragment, splinter, or diffuse into nothingness. For the youth, however, to lose one's essential vitality is merely to stop. For some even self-inflicted death or psychosis may seem preferable to loss of movement; and suicidal attempts in youth often spring from the failure of efforts to change and the resulting sense of being forever trapped in an un-moving present.

The youthful *view of adulthood* is strongly affected by these feelings. Compared to youth, adulthood has traditionally been a stage of slower transformation when, as Erickson has noted, the relative developmental stability of parents enables them to nurture the rapid change of their children. This adult deceleration of personal change is often seen from a youthful vantage point as concretely embodied in apparently unchanging parents. It leads frequently to the conscious identification of adulthood with stasis, and to its unconscious equation with death or nonbeing. Although greatly magnified today by the specific political disillusionments of many youths with the "older generation," the adulthood=stasis (= death) equation is inherent in the youthful situation itself. The desire to prolong youth indefinitely springs not only from an accurate perception of the real disadvantages of adult status

in any historical era but from the less conscious and less accurate assumption that to "grow up" is in some ultimate sense to cease to be really alive.

Finally, youths tend to band together with other youths in *youthful countercultures*, characterized by their deliberate cultural distance from the existing social order, but not always by active political or other opposition to it. It is a mistake to identify youth as a developmental stage with any one social group, role, or organization. But youth is a time when solidarity with other youths is especially important, whether the solidarity be achieved in pairs, small groups, or formal organizations. And the groups dominated by youth reflect not only the special configurations of each historical era but also the shared developmental positions and problems of youth. Much of what has traditionally been referred to as "youth culture" is, in the terms used here, adolescent culture; but there are also groups, societies, and associations that are truly youthful. In our own time, with the enormous increase in the number of those who are entering youth as a stage of life, the variety and importance of these youthful countercultures is steadily growing.

This compressed summary of themes in youth is schematic and interpretative. It omits many of the qualifications necessary to a fuller discussion, and it neglects the enormous complexity of development in any one person in favor of a highly schematic account. Specifically, for example, I do not discuss the ways the infantile, the childish, the adolescent and the truly

youthful interact in all real lives. Perhaps most importantly, my account is highly interpretative, in that it points to themes that underlie diverse acts and feelings, to issues and tensions that unite the often scattered experiences of real individuals. The themes, issues, and conflicts discussed here are rarely conscious as such; indeed, if they all were fully conscious, there would probably be something seriously awry. Different youths experience each of the issues considered here with different intensity. What is a central conflict for one may be peripheral or unimportant for another. These remarks, then, should be taken as a first effort to summarize some of the underlying configurations that characterize youth as an ideal type.

Affective and Interpersonal Transformations in Youth

A second way of describing youth is by attempting to trace out the various psychological and interpersonal transformations that may occur during this stage. Once again only the most preliminary sketch of youthful development can be attempted here. Somewhat arbitrarily I will distinguish between development in several sectors or areas of life, noting only that, in fact, changes in one sector invariably interact with those in other sectors.

In pointing to the *self-society relationship* as a central issue in youth, I also mean to suggest its importance as an area of potential change. The late adolescent is only beginning to challenge his society's definition of him, only

starting to compare his emerging sense of himself with his culture's possibilities and with the temptations and opportunities offered by his environment. Adolescent struggles for emancipation from external family control and internal dependency on the family take a variety of forms, including displacement of the conflict onto other "authority figures." But in adolescence itself, the "real" focus of conflict is 011 the family and all of its internal psychic residues. In youth, however, the "real" focus begins to shift: increasingly the family becomes more paradigmatic of society rather than vice versa. As relatively greater emancipation from the family is achieved, the tension between self and society, with ambivalent probing of both, comes to constitute a major area of developmental "work" and change. Through this work young people can sometimes arrive at a synthesis whereby both self and society are affirmed, in the sense that the autonomous reality-relatedness yet separateness of both is firmly established.

There is no adequate term to describe this "resolution" of the tension between self and society, but C. G. Jung's concept of *individuation* comes close. For Jung the individuated man is a man who acknowledges and can cope with social reality, either by accepting it or by opposing it with revolutionary fervor. But he can do this without feeling his central selfhood overwhelmed. Even when most fully engaged in social role and societal action, he can preserve a sense of himself as intact, whole, and distinct from society. Thus, the "resolution" of the self-society tension in no way necessarily entails

"adjusting" to the society, much less "selling out"—although many youths see it this way. On the contrary, individuation refers partly to a psychological process whereby self and society are differentiated internally. But the actual conflicts between men and women and their societies remain and, indeed, may become even more intense.

The meaning of individuation may be clarified by considering the special dangers of youth, which can be defined as extremes of *alienation*, whether from self or from society. At one extreme is the total alienation from self that involves abject submission to society, "joining the rat race," "selling out." Here society is affirmed but selfhood denied. The other extreme is a total alienation from society that loads not so much to the rejection of society as to its existence being ignored, denied, and blocked out. The result is a kind of self-absorption, an enforced interiority and subjectivity, in which only the self and its extensions are granted reality, while all the rest is relegated to a limbo of insignificance. Here the integrity of the self is purchased at the price of a determined denial of social reality and the loss of social effectiveness. In youth both forms of alienation are often assayed, sometimes for lengthy periods. And for some whose further development is blocked, they become the basis for lifelong adaptations—the self-alienation of the marketing personality, the social alienation of the perpetual drop-out. In terms of the developmental polarities suggested by Erikson, we can define the central developmental tension of youth as individuation versus alienation.

Sexual development continues in important ways during youth. In modern Western societies, as in many others, the commencement of actual sexual relationships is generally deferred by middle-class adolescents until their late teens or early twenties: the modal age of first intercourse for American college males today is around twenty, for females about twenty-one. Thus, despite the enormous importance of adolescent sexuality and sexual development, actual sexual intercourse often awaits youth. In youth there may occur a major shift from masturbation and sexual fantasy to interpersonal sexual behavior, including the gradual integration of sexual feelings with intimacy with a real person. And as sexual behavior with real people commences, one sees a further working through, now in behavior, of vestigial fears and prohibitions whose origins lie in earlier childhood—specifically, of oedipal feelings of sexual inferiority and of oedipal prohibitions against sex with one's closest intimates. During youth, when these fears and prohibitions can be gradually worked through, they yield a capacity for genitality, that is, for mutually satisfying sexual relationships with another whom one loves.

The transition to genitality is closely related to a more general pattern of *interpersonal development.* I will term this the shift from "identicality" to mutuality. This development begins with adolescence[2] and continues through youth. It involves a progressive expansion of the early adolescent assumption that the interpersonal world is divided into only two categories:

first, me and those who are identical to me (potential soul mates, doubles, and hypothetical people who "automatically understand everything"), and, second, all others. This conceptualization gradually yields to a capacity for close relationships with those on an approximate level of "parity" or similarity with the individual.

The phase of parity in turn gives way to a phase of "complementarity," in which the individual can relate warmly to others who are different from him, valuing them for their dissimilarities from himself. Finally the phase of complementarity may yield in youth to a phase of "mutuality," in which issues of identicality, parity, and complementarity are all subsumed in an overriding concern with the other as other. Mutuality entails a simultaneous awareness of the ways in which others are identical to oneself, the ways in which they are similar and dissimilar, and the ways in which they are absolutely unique. Only in the stage of mutuality can the individual begin to conceive of others as separate and unique selves and relate to them as such. And only with this stage can the concept of mankind assume a concrete significance as pointing to a human universe of unique and irreplaceable selves.

Relationships with elders may also undergo characteristic youthful changes. By the end of adolescence the hero worship or demonology of the middle adolescent has generally given way to an attitude of more selective emulation and rejection of admired or disliked older persons. In youth new

kinds of relationships with elders become possible: psychological apprenticeships, then a more complex relationship of mentorship, then sponsorship, and eventually peership. Without attempting to describe each of these substages in detail, the overall transition can be described as one in which the older person becomes progressively more real and three-dimensional to the younger one, whose individuality is appreciated, validated, and confirmed by the elder. The sponsor, for example, is one who supports and confirms in the youth that which is best in the youth, without exacting an excessive price in terms of submission, imitation, emulation, or even gratitude.

Comparable changes continue to occur during youth with regard to *parents.* Adolescents commonly discover that their parents have feet of clay and recognize their flaws with great acuity. Childish hero worship of parents gives way to a more complex and often negative view of them. But it is generally not until youth that the individual discovers his parents as complex, three-dimensional, historical personages whose destinies are formed partly by their own wishes, conscious and unconscious, and partly by their historical situations. Similarly it is only during youth that the questions of family tradition, family destiny, family fate, family culture, and family curse arise with full force. In youth the question of whether to live one's parents' life, or to what extent to do so, becomes a real and active one. In youth one often sees what Ernst Prelinger has called a "telescoped reenactment" of the life of a

parent—a compulsive need to live out for oneself the destiny of a parent, as if to test its possibilities and limits, experience it from the inside, and (perhaps) free oneself of it. In the end the youth may learn to see himself and his parents as multidimensional persons, to view them with compassion and understanding, to feel less threatened by their fate and failings, and to be able, if he chooses, to move beyond them.

Every developmental stage tends to re- evoke, often in a highly selective fashion, themes and conflicts that date from earlier stages. In each individual the weight and origin of the reevoked past will vary, depending on the idiosyncrasies of his experience. But beyond idiosyncratic variations common links seem to join postpubescent development with prepubescent development. For example, the stage of early adulthood involves entry for the first time into the world of work; it thus re- evokes isomorphic issues of competence, industry, and inferiority that were experienced in childhood upon entry for the first time into the world of school.

If we differentiate adolescence from youth, we must reconsider those formulations that see revivified oedipal themes as central to adolescence. More common in adolescence, I believe, is the reawakening of preoedipal concerns focused on the "anal" stage, with its conflicts over autonomy, will, order, control and impulsivity, mossiness and neatness. If we define adolescence, in oversimplified fashion, as involving, above all, emancipation

from dependency on and control by the family, then the isomorphism between the anal phase and adolescence becomes clearer. Each stage entails, at a different level, an effort to move away from controlling and dependency-inducing others toward a more self-controlling and independent position. Thus, during adolescence, behavior and fantasy are commonly dominated by struggles for independence and thinly veiled wishes for dependency, by provocativeness and negativism, by sloppiness and compulsive neatness, by willfulness coupled with irresponsibility—all of which most resemble psychologically the toddler's early efforts to establish self-control and to avoid total control by his parents. Even the proverbial embarrassment of the adolescent, now focused upon his or her incipient adult sexuality, resembles the "shame" of the child during the anal stage.

In youth these anal issues recur, but they are increasingly overshadowed by oedipal themes. In Erickson's terms, the toddler establishes that he has a will of his own; during the oedipal period he learns to take initiative, using that will. In a parallel way the adolescent hopefully achieves emancipation and independence from his family; during youth he confronts the issue of how, where, and when his independent and autonomous selfhood is to be exercised. In the normal course of youthful development, a whole series of conflicts, complexes, and inhibitions whose origins lie in the oedipal phase are therefore reevoked. When youthful development falters, it is often because the inhibitions of the oedipal stage remain so powerful that the

individual is compelled either to reenact them repetitively or to regress to modes of functioning (including cognitive functioning) more characteristic of the three- to five-year-old than of the stage of youth itself.

The tendency among youth to defer actual sexual relationships until the twenties also helps explain the centrality of oedipal themes in this stage of life. Although oedipal issues obviously recur in different forms throughout life, they tend to be reexperienced and reenacted with particular intensity at the point in life when the individual attempts to unite intimacy and sexuality in a real, instead of a fantasied, relationship. At this juncture the powerful, if usually unstated, taboos laid down within the child's family, prohibiting the joining of overtly erotic and affectionate ties, are powerfully reawakened. For this reason the first real sexual relationships are more often than not psychologically triadic rather than simply dyadic. Same-sex friends and rivals are often as much in the forefront of consciousness during the beginning of sexual relationships as is the sexual partner himself or herself. Indeed, the sexual partner may remain shadowy or vague in comparison to the dreaded and feared rivals with whom one competes for his or her affection; just as often, the initiation of sexual relationships appears to require a permissive contemporary, perhaps more sexually experienced or perceived as more "mature," to whom one reports in more or less graphic detail the sexual and interpersonal complexities of the new sexual relationship.

These triadic relationships often appear flagrantly neurotic, and can be, if they do not eventually yield to a more truly dyadic sexual relationship in which the real existence of the partner is central rather than peripheral. But the longitudinal clinical study of young men and women in the process of beginning sexual relationships suggest that such triadic "oedipal" relationships are so frequent as to be virtually normal in educated youth. Indeed it may be that this reenactment of triangular love relationships permits some youths to work through in actual behavior childhood feelings of inferiority in love relationships or childhood fears that heterosexual relationships will result in devastating reprisals from same sex rivals.

Having emphasized that these analytically separated lines of development are, in fact, linked in the individual's experience, it is equally important to add that they are never linked in perfect synchronicity. If we could precisely label one specific level within each developmental line as distinctively youthful, we would find that few people were "youthful" in all lines at the same time. In general, human development proceeds unevenly, with lags in some areas and precocities in others. One young woman may be at a truly adolescent level in her relationship with her parents, but at a much later level in moral development; a young man may be capable of extraordinary mutuality with his peers, but still be struggling intellectually with the dim awareness of relativism. Analysis of any one person in terms of specific sectors of development will generally show a simultaneous mixture of

adolescent, youthful, and adult features. Once again the point is that the concept of youth here proposed is an ideal type, a model that may help understand real experience but can never fully describe or capture it.

Ideology in Youth

Of all stages of life, youth is the most ideological. The potential for the development of ideology rests upon affective and cognitive changes that may begin in adolescence but that extend far beyond it. In the ideological preoccupations of youth are focused, condensed, and expressed concerns of diverse origins: psychosexual and historical, interpersonal and societal, defensive and generational, affective and ethical. It is therefore arbitrary and misleading to separate ideology formation from those affective, psychosexual, and interpersonal transformations discussed in the previous section. All are intertwined in the effort, often vehement and agonized, to develop what Erikson, quoting George Bernard Shaw, termed "a clear view of the world in the light of an intelligible theory."

As commonly used, "ideology" has two distinct meanings. Sociologists and intellectual historians use it to refer to a public body of shared doctrine, belief, evaluation, and exhortation, transmitted from one individual or one generation to another and embodied in collective values, symbols, theories, and norms. For psychologists and psychiatrists, however, the term has a

primarily individual referent: it points to the individual's developing world view, conscious or unconscious, shared or idiosyncratic, especially seen as a defensive and expressive system. Thus, on the one hand, the intellectual historian may interpret ideology only as a cultural cement that binds together a society, while the individually-oriented psychiatrist may consider ideology only a "projective system" that expresses the complexes and conflicts of early childhood.

An adequate understanding of ideology during youth must include both perspectives. The sociologist is right in underlining that most of the ingredients of any individual's ideology are borrowed from others, from his historical tradition, from his culture. But the psychologist is right in emphasizing that the synthesis of these "borrowed" elements is built around enduring and often idiosyncratic themes, conflicts, defenses, and talents within the individual himself. The development of a world view is thus a battleground on which individual and sociohistorical issues come together and are sometimes resolved. Ideology lies at the juncture between the individual and his society and history; ideology formation entails at best a synthesis of elements that are uniquely personal with ideas, symbols, and values that connect the individual to his community and to his historical tradition.

The realm of abstract ideas, interpretative principles, theories, and

symbols, being farthest from observable reality, is most intimately related to the deepest themes of the psyche. Those who have studied the psychodynamics of individual ideologies have shown that they integrate, synthesize, and to a degree "rationalize" intrapsychic issues ranging from deeply rooted conflicts to preferred adaptive styles. The assumptions and perspectives from which any individual perceives and interprets the world indeed perform important defensive functions of intellectualization and rationalization.- But to stress only the expressive or defensive element in ideology development neglects the roots of this process in cognitive, intellectual, and ethical developments that are themselves powerfully adaptive; it only ignores the functional role of ideology in orienting the individual in a world that might otherwise be overwhelming in its chaotic complexity. Ideology thus provides not only a defense against unacceptable impulses or a way of explaining away unattractive impersonal characteristics, but a framework within which the individual can relate himself simultaneously to his own personal history and to the history of his society and generation.

The development of an ideology that transcends the internalized prescriptions, prohibitions, and perspectives of childhood is made possible and necessary by cognitive, intellectual, and ethical restructurings of the personality that can occur after adolescence. The most crucial of these is what Inhelder and Piaget term the capacity for formal operations— namely, the

ability to perform hypothetico- deductive operations whereby the observable and concrete world of the real comes to be seen as a subset of the world of the possible. In Piaget's middle-class Swiss subjects this capacity is generally attained in rudimentary form around the time of puberty. But as Piaget notes, the full integration of the capacity for formal operations is often long deferred. At issue in this integration is a gradual "decentering," a transition from an exclusively egocentric mode of formal operations to an exercise of this capacity in a context that includes some acceptance of the gap between the real and the possible, the actual and the ideal.

Many of the ideological struggles of youth are built around the painful process of attaining a more integrated use of formal operations. It is as if the emergence of this capacity overwhelmed many adolescents with the terrifying awareness of desirable personal and societal possibilities that are not, and may never be, actualized. During youth this conflict between the ideal and the actual is worked on, and at best worked through, with regard to both self and society. Vis-a-vis the self, the conflict entails an awareness of all that one might conceivably be (and become) but is not (and will never be). It therefore involves a growing awareness and acceptance of one's human limitations. At the level of society the struggle involves confrontation with the gulf between societal creed and deed, a gulf probably widest in societies like America whose ideals are so frequently and nobly stated but so rarely achieved. In most societies "mature adults" are ordinarily expected to have

accepted the gap between the real and the ideal with regard to both self and society.

In youth such a "mature acceptance" of the nonideal nature of psychological and social reality has not been achieved. For this reason youth is the stage of life where the demand for both psychological and social change is most compelling. Nor should this demand be automatically dismissed as a sign of immaturity. On the contrary, one may ask whether the acceptance of the imperfection of self and society expected of adults does not constitute a real retrogression from the idealism of youth. In many adults this "acceptance" has been so excessive as to leave them with a lifelong fear that they have betrayed the best in themselves or "compromised" their own youthful vision of a better society. Paradoxically, how one later reacts to "youthful idealism" and its common subsequent waning depends largely on the ideological position attained in youth, for one of the central functions of ideology formation is to come to terms with the gap between the real and ideal. And how one does this determines where on the spectrum between revolutionary and organization man one is likely to spend the remainder of one's life.

In some youths there also occurs a further stage of cognitive development that goes beyond the integration and consolidation of formal operations. Jerome Bruner has suggested that beyond the stage of formal

operations there may lie a further stage of "thinking about thinking." In practice just such a stage can be observed in some intellectual and introspective youths. It involves a breaking away of thought from specific mental processes, a consciousness of consciousness, a separation of the phenomenological "I" from the contents of thought.

This breakaway of the phenomenological ego permits youth to engage in phenomenological games, intellectual tricks, and kinds of creativity that are rarely possible during adolescence itself. And as consciousness becomes an object of consciousness, it also becomes a potential target of manipulation, a state to be changed through transformations of self and environment. Throughout history there have always been some rare youths who deliberately sought to alter consciousness, using the instruments provided by their culture and their technology. Today this focus on alternation of consciousness involves not only agents like hallucinogenic drugs but a return to ancient forms of consciousness-changing like meditation, yoga, and Zen. Finally the consciousness of consciousness makes possible one of the most frightening states experienced in youth, the disappearance of the phenomenological ego in an endless regress of awareness of awareness of awareness.

Given a cognitive capacity for formal operations, regular stages of intellectual and moral development can be observed. William Perry has

recently provided a description of the stages of potential intellectual development that may occur during late adolescence and youth. Perry's work emphasizes the complex tradition from epistemological dualism to an awareness of multiplicity and to the realization of relativism. Relativism, in turn, may give way to a more "existential" sense of truth, culminating in what Perry terms "commitment within relativism." Thus, during youth we expect to see a passage beyond simple views of right and wrong, truth and falsehood, good and evil to a more perspectival view. And as youth proceeds, we may look for the development of commitment within a universe that remains epistemologically relativistic. The stages defined by Perry—dualism, multiplicity, relativism, and commitment within relativism—are a description of a developmental line that most individuals clearly do not complete to its end. In particular Perry underlines that the transition to the stage of relativism is fraught with difficulty, and that many young men and women, vaguely sensing the uncertainties of a relativistic universe, may temporize or return to earlier certainties.

Lawrence Kohlberg's work on moral development provides another paradigm of changes that occur only in youth if they occur at all. Summarized oversimply, Kohlberg's theory of the development of moral reasoning distinguishes three broad stages. The earliest or *preconventional* stage involves relatively egocentric concepts of right and wrong as that which one can do without getting caught or as entailing primitive notions of reciprocity

("I'll scratch your back if you'll scratch mine"). This stage is followed, usually during later childhood, by a stage of *conventional* morality, during which good and evil are identified with the concept of a good boy or a good girl (that is, with conformity to role expectations), or, at a somewhat higher level, with standards of the community and concepts of law and order. In the conventional moral stage, which parallels Perry's dualistic stage, morality is perceived as objective, as existing "out there." Kohlberg's third and highest stage of moral reasoning is termed autonomous or *postconventional*—if development into this stage occurs at all, it is most likely to occur during youth. This stage involves more abstract moral reasoning that may lead the individual into conflict with conventional morality. The lower level of the postconventional stage involves the definition of right and wrong in terms of the long-term welfare of the community. This type of reasoning can be called the social contract level, in that it construes moral rules and moral behavior as ultimately determined by considerations of the well-being of all members of a society. Unlike conventional moral reasoning, this level views moral codes, rules, and laws not as objective and eternal, but as manmade, changeable, and amendable.

In the highest (and final) postconventional level, the individual affirms general moral principles that may transcend not only conventional morality but even the social contract: this level confronts the possibility that even rules made in the public interest may be unjust. At this level general precepts,

stated at a high level of generality, are seen as personally binding, though not necessarily "objectively" true. However these precepts are stated—as the Golden Rule, the sanctity of life, the Kantian categorical imperative, the promotion of human development, or the concept of justice itself—they share their universalism and their search for moral structures that are applicable to all situations and persons regardless of time, place, society, station, and situation. At the level of personal principles the individual not only may find himself in conflict with existing concepts of law and order but also may at times consider democratically arrived at laws unjust if they violate his universalistic principles.

The work of Piaget, Perry, and Kohlberg is not intended as a comprehensive account of development, or even as an inclusive analysis of the development of ideology. Each sets itself a more limited task: the delineation of the sequences of development in a particular sector. For this reason the parallels between the three accounts are the more striking. All three accounts emphasize the centrality of the transition from the empirically, culturally, or morally "given" to a new mode of functioning that transcends the given. Stated more psychodynamically, all three suggest the limitations of "internalization" as a mechanism of learning beyond adolescence and point to the possibility of "synthetic" developments that go beyond and may be in conflict with inductive generalizations, received truths, or community moral standards.

Equally important, all three accounts emphasize the hazards that accompany the transition from the given to the synthetic, from the traditional to the formulative. Perry notes that the movement from dualism to relativism is fraught with special dangers that result from renouncing the certainty inherent in a dualis- tic perspective for the uncertainty of a universe where truth is perspectival, and where a commitment to a perspective requires an "existential" affirmation for which the individual must accept personal responsibility. Confronted with an imminent awareness of relativism, Perry argues, many young men and women temporize, stagnate, or retreat to earlier forms of dualism, now the more dogmatically held because dimly apprehended relativism threatens to undercut certainty. It follows that no dogmatism is more fierce than that of the man who has paused on the threshold of relativism to reassert the verity of the world view from which he was moving or the transcendental truth of some new ideology.

Kohlberg describes a similar process in moral development. In longitudinal studies of young American men, Kohlberg and his associates have observed a phenomenon they term the "Raskolnikov Syndrome"—a moral regression that may occur as the individual begins to question the adequacy of conventional moral structures. To be sure, many young men and women seem to make the transition to post- conventional moral reasoning with little apparent difficulty. But among those who begin to challenge conventional moral codes, a number "regress" to preconventional moral

structures rather than (or before) moving on to the affirmation of autonomous postconventional moral principles. In Perry's terms it is as if confrontation with the relativism, and to that degree the arbitrariness, of the moral structures accepted by the socializing community (and until then internalized) pushes some people back to a kind of "anything goes," preconventional moral framework. Both Perry and Kohlberg are thus describing, in different terms, a process whereby the transition from the "conformist" or "conscientious" position to a more "autonomous" or "individuated" perspective is aborted, resulting not in further development but in a return to more familiar, primitive structures that also negate the validity of conventional moral norms and dualistically conceived truths.

Although the language in which this "cognitive regression" is described may be unfamiliar to the clinician, the process itself is observed in clinical practice and constitutes the cognitive core for much of the ideological and psychological turmoil seen in youth. Especially in times of cultural crisis and widespread exposure of injustice, abrupt confrontation with the arbitrariness and hypocrisy that exist in the social world (or in the individual) may "force" a youth back to the only nondualistic, nonconventional position he knows, namely, an earlier view of truth as that which is convenient and of morality as that which avoids punishment and increases pleasure. When this regression occurs in large numbers of young men and women, it tends to become ideologized at a collective level and institutionalized in youthful

countercultures. The consequence is a scathing collective attack on conventional pieties, and an explicit sanctioning of behavior that scandalizes the most sacred norms and taboos of those who adhere to dualistic truths and conventional moralities. In a society that traditionally emphasizes the sanctity of property, for example, property is likely to be singled out for special attack by the destruction of property as an act of ideological affirmation, by the deliberate avoidance of possessions, or by a view of theft (the "rip-off") as a morally justified or noble act.

Accounts of the cognitive, intellectual, and moral aspects of ideology formation necessarily exclude all those other noncognitive conflicts and confrontations that serve as catalysts for and are intertwined with cognitive, intellectual, and ethical development in youth. But if we study real individuals in depth over an extended period, they rarely speak in exclusively cognitive, intellectual, or moral terms; and if they do, we rightly suspect that we are hearing only a part of the story, which serves as a "cover" for that which is left unmentioned. In practice, then, the cognitive, intellectual, ethical changes that underlie ideology formation are intertwined with the psychosexual, interpersonal, and affective developments discussed earlier. What psychologists conveniently separate into "affective" and "cognitive" are interdependent at all stages of life. For example, to imagine and strive toward a truly mutual relationship with another person presupposes the cognitive capacity of formal operations; but to achieve some degree of mutuality with a

loved one, in turn modifies, "decenters," extends and consolidates that purely cognitive capacity.

As a rule the catalysts for intellectual and moral development in youth are found in realms other than the purely intellectual and moral: they may include an ambivalent realization that one's parents are limited, unhappy people; a prolonged immersion in an alien culture; falling in love with someone whose world view is very different from one's own; membership in a countercultural group devoted to an attack on conventional truths, policies, or moral codes; realizing (from friends, enemies, drugs, or psychotherapy) that one's pretensions to virtue are fraudulent; growing awareness of one's interpersonal, sexual, moral, or physical inhibitions; a concrete confrontation with the gap between public practice and public preaching; and so on. In the end human development is neither affective nor cognitive, but both; only as a matter of analytic convenience or research strategy can we separate its aspects—and then, hopefully, as a preface for showing their relationship.

To describe further the vicissitudes of the development of ideology during youth is simply to describe youth itself. Erikson's' insightful accounts of identity, ideology, and ideological innovators illustrate and expand the points made here: the interweaving of the uniquely personal with the generational, historical, and universal; the way in which the emergence of new cognitive, intellectual, and ethical capacities spurs new confrontations,

advances, and regressions; the agonized and often prolonged shock that follows the "discovery" of the relativism of truth and the arbitrariness of conventional moral structures; the possibility of a return to old dogmatisms (or the creation of new ones) in the search for a world view to replace the dualistic security of childhood; the crucial role of ideology in uniting the members of youthful groups who are undergoing parallel developmental struggles.

The foregoing discussion of ideology development should be read in the light of my earlier comments on the contingency of psychological development, for there is clear evidence that the majority of young men and women between the ages of 18 and 30 do *not* pass through most of the stages I have outlined. For most adult men and women it is most precise to say that ideology is borrowed rather than developed. These are those whom William James long ago termed the "once-born," who accept with little anguish or reexamination the cultural traditions learned in their early lives.

The evidence for the contingency of development is especially conclusive in the realm of ideology. Kohlberg and his associates have found that only a minority of teen-agers possess the cognitive capacity for formal operations; and if higher levels of this capacity are measured, then a majority of all contemporary middle-class American adults lack it. Studies in a rural Turkish village indicate that virtually no adults posses this capacity. It follows,

as Kohlberg notes, that the majority of chronological teen-agers in America arc not cognitive adolescents—if, that is, we accept the prevailing view that cognitive development is both a companion and a catalyst for psychological adolescence. Since all the ideological developments of youth discussed here presuppose a highly developed capacity for formal operations, we must conclude that real ideology development occurs only in a minority of young Americans.

This conclusion is empirically substantiated in the work of both Perry and Kohlberg. Perry found that only a few of the college students he studied had moved to his highest level of intellectual functioning, commitment within relativism. And Kohlberg, whose research methods enable him to measure the individual's level of moral reasoning, finds that the majority of middle-class college students have not moved beyond conventional structures at the age of 24. Among working-class subjects (and their fathers) the proportion using postconventional moral reasoning is even lower. Other studies indicate that for both male and female college students, the modal moral position is the conventional position.

Studies like these require us to define both adolescence and youth as "contingent" from a cognitive, intellectual, moral, and ideological point of view—and probably in other respects as well. They remind us again that "youth" as here defined is in no sense a universal stage of development, even

among the advantaged, educated young men and women in economically advanced societies who occupy so much of psychiatrists' time. These studies further impel us to remember that it is possible and normal for men and women to live—and to live well, healthily, and happily—at the stage of concrete operations, with the dualistic view of truth, and with a conventional morality. It seems that most of mankind has always lived this way and that, as a result, most men and women have not experienced the full force of the ideological tensions that constitute a central part of youth. Youth involves the actualization of the usually latent human potential for departure from societal certainty, for questioning of conventional moral codes, for imagining a world different from that which exists, and for thinking about thought.

Psychopathology in Youth

The developmental component in psychological disorders is often neglected or discussed solely by noting that the origin of pathological symptoms often lies in crises, conflicts, or feelings that date from earlier developmental stages. But psychological disturbances are also related to, organized around, and precipitated by the psychological issues and conflicts of the developmental stage *during which they occur.* Thus, the relationship between development and psychopathology is at least fourfold. First, developmental "work" left undone or incompletely consolidated at one stage of life compromises later development and may produce significant

psychopathology during later stages. Second, psychological disturbances necessarily occur during a stage of life, and their content is therefore shaped by stage- specific themes, changes, and conflicts; third, psychopathology is often triggered by blockings, foreclosures, or impasses in the developmental work faced by the individual at a given stage of his life; and finally, normal development entails what Anna Freud and Peter Bios have termed "regression in the service of development" and therefore involves a recapitulation, reenactment, and re- experiencing of the past that, if it proves too deep and enduring, may be termed pathological. A comprehensive discussion of psychopathology during any stage of life should ideally consider all of these relationships.

During youth such protean human disturbances as *depression* are both precipitated by and organized around the themes that assume special prominence in this stage of life. I earlier noted the centrality to youth of continuing movement, the consequent abhorrence of stasis, and the unconscious identification of immobilization with death. Depressions during youth are strongly influenced by these themes. The immediate catalyst of many youthful depressions is a sense of development impasse, stasis, or stagnation, a feeling of being "stuck," "trapped," or "blocked"—whether spatially, temporally, or developmentally. Especially dysphoric is the experienced failure of efforts to move, however movement may be defined by the individual. For example, in those imbued with an achievement ethic,

achievement itself may be equated with motion, and failures to achieve are therefore seen as portents of a life without further mobility. Similarly, when efforts at self-reform and self-improvement fail, they may produce depressions associated with a sense of being "locked into" an abhorred personality style or character structure. Such depressions far exceed "realistic" reactions to failure: they evoke deeper fears of immobilization and reawaken primitive anxieties associated with deprivation. The individual feels himself unresponsive, frozen, immobilized, effectively "dead."

Whatever the underlying etiology of youthful depressions, the most common response is to attempt to regain momentum. All types of movement are unconsciously equated: geographic movement and social mobility can be a substitute for psychological change; the effort to move others may be a response to the fear of being trapped oneself; the pressure for social reform and revolution may be animated by a sense of personal impasse and stagnation. Because movement is the quintessential youthful antidepressive maneuver, youthful depressions tend to be agitated, restless, jittery, and frantic, often accompanied by hypomanic ideation or activity. Today, with the ease of transportation, geographic motion— across the continent or around the world—is a favored and sometimes successful self-therapy. So, too, is rapid motion—the fast car, the racing motorcycle, the fleeting jet. And finally, the contemporary availability of a variety of drugs, from marijuana to amphetamines, which speed up experience or relieve the depressive

flattening of affect and perception, provides yet another way of overcoming, at least temporarily, the loss of a sense of motion that is central to a feeling of vitality in youth.

Serious thoughts of *suicide,* suicidal gestures, and suicide attempts in youth are commonly related to these issues. Few young men and women pass through this stage of life without considering, whether distantly or concretely, the possibility of suicide. Serious suicidal thoughts or attempts are often animated by the fantasy that suicide will produce change, relieve an unbearable sense of being immobilized, and thus generate new movement. In working with severely depressed youths, it is, of course, necessary to explore the varied idiosyncratic meanings of suicide. But it is equally important to acknowledge that suicidal thoughts may be an (irrational) expression of the feeling that to remain "stuck" in one's present situation is untenable, that it is essential somehow to move. Indeed, the two most common causes of death among youth— accidents caused by speeding and suicide— must be understood not only as efforts to end life but as misguided attempts to regain a sense of inner momentum, and with it a feeling of "really being alive." If so, then it is the inner sense of already being psychologically dead that paradoxically impels many youths into activities that lead to physical death.

The special youthful potential for phenomenological estrangement also influences psychological disturbances during this stage. Especially for

interpersonally isolated youths, estrangement may reach pathological proportions of acute *depersonalization and derealization.* The individual searches desperately for efforts to connect up with others, with himself, with meaningful groups, admired persons, or valued historical traditions. Even to the casual observer these efforts may seem frantic and driven not by affirmative developmental goals but by a growing sense of unreality and disconnection. The outcome of periods of acute estrangement depends mostly on the actual availability to the individual of others who are capable of understanding him, for the only lasting remedy for feelings of estrangement is the experience of real relationships. Those who are severely inhibited in their dealings with others therefore run a special danger of an acute sense of estrangement, sometimes culminating in periods of truly psychotic depersonalization.

The normal omnipotentiality of youth also may be incorporated into psychological disturbances. Driven by a fear of estrangement, a young man or woman may be impelled to *omnipotent fantasies of total transformation* of himself, others, or the world. Youth is capable of a special grandiosity that rests on the need to possess total control over one's destiny or over the fates of others. Adult recognition of limitations on personal ability and power tend to be absent from much youthful thought and planning. In working with youths who assume a kind of infantile omnipotence in dealings with the world, it is important not to undercut these fantasies too harshly, for these

may be desperately needed to escape far more frightening feelings of estrangement, helplessness, and alienation.

In discussing ideology in youth, I emphasized the possibility of regression in ideological development. Clinicians are often too quick to apply pathological labels to youthful ideologies that seem strange, unfamiliar, or provocative. The search for a comprehensive world view may lead to ideas that seem bizarre, schizoid, or even psychotic to an outside observer. Such ideologies often bear little relationship to the "consensual reality" of most adults or to the "mature perspective" of most psychotherapists. Especially today, any attempt to define pathology in the realm of ideology must rest on a thorough knowledge of the prevailing variants of the youth culture. For example, an intelligent youth who in 1950 took astrology as a serious guide to life would have been considered psychotic; in the 1970's he is more likely to be simply a faithful member of the counterculture.

None of this should blind us to the existence of truly *disturbed ideology formation,* which may be part and parcel of bizarre, destructive, or self-destructive behavior. Just as the formation of ideology cannot be separated from other aspects of development during youth, so disorders in development, thought, and functioning are almost invariably reflected in ideology. Today the proliferation of exotic countercultural groups, cults, and communes allows many disturbed youths a more or less sanctioned

ideological expression of their own conflicts, and at times a protected context where they can navigate an unusually troubled stage of development.

The greatest danger for clinicians who work with ideological youth, however, is the temptation to view ideology solely in its "psychological," expressive, and defensive role. It is indeed accurate to say that each youth "uses" the ideological alternatives of his world as an arena on which he can "act out" his developmental conflicts. But if we say no more than this, we neglect all the positive functions of ideology in individual as well as collective life. At an individual level the development of an ideology beyond dualism and conventional moralism makes possible, indeed demands, personal commitment to a world view that transcends the circumstances of childhood and of the previous generation. And as Erikson has pointed out, ideology at a collective level can express and give meaning to widespread conflicts, common character traits, and a shared awareness of the disparity between the real and the ideal. Thus, the therapist who works with youth does well to recognize that, whatever the pathologies of ideology in a patient, the goal of therapy must not be the eradication of ideology, but support for those processes that will enable the individual to develop an ideology that both expresses his unique selfhood and unites him to the rest of mankind.

Perhaps the most common disturbance in youth lacks any diagnostic label: I will call it an *interpersonal imbroglio.* Characteristically involving at

least three people, it fuses feelings of rivalry, identification, competition, symbiosis, sexuality, ambivalence, splitting, projection, and obsessionality in one embroiled relationship—all strongly influenced by oedipal fantasies and reenactments.

These interpersonal situations have a number of common features. They generally involve a core dyad locked in ambivalent intimacy and hostility, together with a third person who may be friend, rival, and competitor (or all of these things) of one or both of the core partners. All parties involved are likely to acknowledge that the situation is a "mess": the partners generally believe that they are temperamentally incompatible; the third party may be explicitly being "used" by both partners; or the couple itself may be organized primarily around shared fantasies about the "outsider," who is psychologically more important to them than their own relationship. A sense of doom hangs over such relationships, with everyone sensing that a rupture must eventually come. But even though the impossibility of the relationship is openly acknowledged, it tends to drag on interminably, with no one able to make (or sustain) a real break. Guilt, neediness, identification, genuine affection, fears of isolation, the hope of change, the fantasy of omnipotentiality, and a host of other factors are the glue that makes these triads so sticky.

When it is possible to explore in depth the fantasies that animate and

are evoked by such imbroglios, oedipal themes predominate. A young woman who alternates between two lovers—one assertive and aggressive, the other quiet and sensitive—may be struggling to unify a split in her image of her father, all the while avoiding the guilt that would be aroused by a relationship with a "whole man." The young man who sustains an unhappy affair with a married woman often turns out to be far more preoccupied with his fantasies about the husband than with his lover. Finally these situations tend to be obsessionally preoccupying to everyone concerned, evoking and focusing conflicts at every psychological level from every stage of life. Sleepless nights, tears of pain, rage, and frustration, anxiety-laden reunions, and joyous if brief reconciliations are the stuff of which they are made.

Viewed developmentally, the interpersonal imbroglio can be a way station on the road to greater intimacy and mutuality. But so happy an outcome is never assured; and even at best, the participants tend to experience enormous anguish in the process. Because oedipal themes play so central a role in these relationships, those involved often persist in impossible relationships almost indefinitely, and if the relationship finally ends, they may compulsively seek out another equally entangled imbroglio. At times, however, working oneself out of such a relationship may also permit a working through of the inner conflicts enacted in it, enabling the individual to enter into less conflict-filled love relationships. Viewed several months or years later, then, such imbroglios (retrospectively recalled as "unhappy

affairs") may be seen to have performed a positive role in freeing a youth from oedipal fears, inhibitions, and fantasies that stood in the way of any prolonged intimacy.

The most dramatic psychological disturbance in youth is the *acute psychotic break.* Psychotic episodes in youth often have a sudden onset in young men and women with no previous history of overt psychological disorder. A careful reconstruction of the events that led up to the psychotic break, however, often reveals a common pattern. The beginning of disturbance dates from an experience of acute upheaval following a loss or separation. The individual reacts to the loss by isolating himself from anyone who might enable him to express or test his fantasies, ideas, and feelings. Upset and isolated, he becomes even more ideational; reads, writes, or introspects with extraordinary intensity; and is at times manically productive. As time passes, he experiences flights of ideas accompanied by a sense of "breakthrough"—of achieving extraordinary and often genuine insights into himself, others, or society. The sense of breakthrough, however, may lead to a loss of inner control: ideas come too fast, sleep is impossible, the mind races, the insights achieved cannot be verbalized. Often within a period of hours or days, there follows a more drastic sense of breakdown of previously established boundaries between self and world, inner and outer, conscious and unconscious, fantasy and reality. As these boundaries crumble, confusion mounts and the earlier sense of omnipotentiality, movement, breakthrough,

and insight gives way to a feeling of confusion, disorientation, and even suicidal panic. The process may culminate in florid delusions, convincing hallucinations, and organized paranoid ideation.

An account of the prepsychotic experience of those who have acute schizophrenic episodes in youth is not an adequate account of the etiology of these disturbances.[3] But an effort to understand the immediate precursors of a psychotic episode may be vitally important in therapy, for the insights achieved in the prepsychotic period may contain important truths about the individual's problems and conflicts, however indirectly, symbolically, or incommunicably they were stated. The sense of "too much, too fast" in the prepsychotic phase may be a precise description of the experience of being overwhelmed by recollections and reexperiencings of episodes and fantasies that are crucial in his development. It is therefore important not simply to write off psychotic thoughts and behaviors as "crazy." If we study those many individuals for whom a "prepsychotic" phase does not culminate in a psychotic episode, one factor that differentiates them is their capacity to formulate, organize, and communicate the excitement and breakthroughs of the "prepsychotic" period. Even as the therapist explores the more distant antecedents of the psychotic episode, he should try to help the patient to unravel, decipher, and communicate whatever was valid in the psychotic experience itself.

Finally, no discussion of disorders in youth today can be complete without mentioning the interweaving of individual disturbances and youthful countercultures. As more and more of those between the ages of 18 and 30 enter this stage of life, we have witnessed the flowering of an enormous variety of youthful countercultures, often transient in ideology, membership, and existence. These countercultures, whose existence is rapidly disseminated by the mass media, provide a haven and at times a kind of therapy for many youths, including some whose development is highly disturbed. What Erikson aptly termed a "psycho-social moratorium" has always been a characteristic of youths whose growth was uneven and troubled. But in the past such moratoriums tended to be individually negotiated and culturally unsanctioned (unless we consider higher education a form of moratorium, which it clearly still is for some). But today such moratoriums are increasingly collective rather than private. Countercultural groups and movements act as special magnets for two kinds of youths: those whose development is more "advanced" than that of their contemporaries, and those whose development requires a shorter or longer period of "regression," recapitulation, and reexperiencing, preferably in the company of others navigating a comparable developmental course.

Contemporary countercultural groups tend to define themselves by opposition to or isolation from the surrounding culture. As a result they share many of the commonly observed tendencies of all small groups:

encapsulation, lack of reality testing, rejection of outgroup members, the development of special characteristics of their youthful members, often producing at a group level behavior and ideology that would be considered pathological if it occurred at an individual level. To some outsiders many such groups appear to demand acceptance of a delusional group ideology, to encourage provocative, destructive, or dangerous behavior, and to promote pathological interpersonal relationships. Highly disturbed individuals are indeed drawn to such groups; but so, too, are youths who are in other contexts quite sane. The result may be a kind of group-induced "pathology," even in the absence of individual psychopathology in group members.

Immersion in a countercultural group obviously may be anything but helpful for some disturbed (or not so disturbed) youths. But for others these groups may in the long run serve an adaptive and developmental role. One study of young men and women involved in the East Village "hippie" community in the late 1960's found that the average member stayed less than two years, that the majority eventually returned to their homes and reentered the educational process from which they had dropped out, and that only those who were highly disturbed or highly creative (or both) remained for longer periods. For the remainder the "hippie" world seems to have served as a collective psychosocial moratorium, a shared "developmental regression" that permitted them to work out and work through some of their inner conflicts. The rapid turnover in youthful communes, political groups, and the

like suggests that these may perform a comparable developmental role for certain of their members.

I hope that these comments on the psychopathology of youth have made clear the fuzziness of the boundary between significant disorder and normal developmental turmoil during this stage of life. Much that would be considered ominous at other stages is routine and without prognostic implications during youth. At all stages of life, development proceeds from conflict, entails turmoil, and often requires the capacity to regress before moving forward. But during youth conflict, turmoil, and regression may last not for weeks or months but for years. Schizoid ideation, hypomanic locomotor restlessness, acute depression, an exaggerated sense of illumination, grandiose but unrealistic plans to change the world, serious suicidal thoughts, tormented interpersonal relationships—all are common. They themselves, their peers, and their elders do much harm to those in this phase of life by prematurely labeling as "pathological" routine developmental turmoil and retrogression. During youth, even more than during other stages, a step forward may have to be preceded by a step backward, and the absence of turmoil may be a symptom not of serenity but of foreclosure.

As a rule most disturbances during youth have a good prognosis; many and perhaps most work themselves out without special therapy. The study of youths who are not patients provides examples of young men and women

whose self-prescribed "therapies," however remote from the traditional modalities of formal psychotherapy, prove highly successful. People were helping themselves and each other long before "psychotherapy" was invented; and they continue to do so, even today, in ways that often defy the explanatory power of our psychological theories.

Those who do work as therapists with troubled youths may therefore need certain special qualities: humility with regard to formal psychotherapy as the preferred modality of treatment; respect for the ultimate integrity of the patient, however disturbed his behavior may be; a capacity to focus on the stage-specific ingredients in the patient's disturbance along with its more distant etiology; a willingness to be fallible, direct, and honest with the patient; and, above all, an absence of any illusions of omniscience or omnipotence. Whatever the therapist's own ideological persuasion and techniques, it may be that he helps his youthful patients most by providing them with a real and honest human relationship with another person who has more or less successfully weathered the turmoil of youth.

What Youth Is Not

A final way to clarify the meaning of youth as a stage of life is to make clear what it is not. For one thing youth is not the end of development. I have described the belief that it is—the conviction that beyond youth lie only

stasis, decline, foreclosure, and death—as a characteristically youthful way of viewing development, consistent with the observation that it is impossible truly to understand stages of development beyond one's own. On the contrary, youth is but a preface for further transformations that may (or may not) occur in later life. Many of these center around such issues as the relationship to work and to the next generation. In youth the question of vocation is crucial, but the issue of work—of productivity, creativity, and the more general sense of fruitfulness that Erikson calls generativity—awaits adulthood. The youthful attainment of mutuality with peers and of peerhood with elders can lead to further adult interpersonal developments by which one comes to be able to accept the dependency of others, as in parenthood. In later life, too, the relations between the generations are reversed, with the younger now assuming responsibility for the elder. Like all stages of life, youth is transitional. And although some lines of development, such as moral development, may be "completed" during youth, many others continue throughout adulthood.

It is also a mistake to identify youth with any one social group, role, class, organization, or position in society. Youth is a *psychological* stage; and those who are in this stage do not necessarily join together in identifiable groups, nor do they share a common social position. Not all college students, for example, are in this stage of life: some students are psychological adolescents, while others are young adults—essentially apprentices to the

existing society. Nor can the experience of youth as a stage of life be identified with any one class, nation, or other social grouping. Affluence and education can provide a freedom from economic need and an intellectual stimulation that may underlie and promote the transformations of youth. But there are poor and uneducated young men and women, from Abraham Lincoln to Malcolm X, who have had a youth, and rich, educated ones who have moved straightaway from adolescence to adulthood. And although the experience of youth is probably more likely to occur in the economically advanced nations, some of the factors that facilitate youth also exist in the less advanced nations, where comparable youthful issues and transformations are expressed in different cultural idioms.

Nor should youth be identified with the rejection of the status quo, or specifically with student radicalism. Indeed, anyone who has more or less definitively defined himself as a misanthrope or a revolutionary has moved beyond youthful probing into an "adult" commitment to a position vis-a-vis society. To repeat: what characterizes youth is not a definitive rejection of the existing "system," but an ambivalent tension over the relationship between self and society. This tension may take the form of avid efforts at self-reform that spring from acceptance of the status quo, coupled with a sense of one's own inadequacy vis-a-vis it. In youth the relationship between self and society is indeed problematical, but rejection of the existing society is not a necessary characteristic of youth.

Youth obviously cannot be equated with any particular age range. In practice most young Americans who enter this stage of life tend to be between the ages of 18 and 30. But they constitute a minority of the whole age- grade. Youth as a developmental stage is emergent; it is an "optional" stage, not a universal one. If we take Kohlberg's studies of the development of postconventional moral reasoning as a rough index of the "incidence" of youth, less than 40 per cent of middle-class (college-educated) men, and a smaller proportion of working-class men, have developed beyond the conventional level by the age of 24. Thus, "youths" constitute but a minority of their age group. But today those who are in this stage of life largely determine the public image of their generation.

Admirers and romanticizers of youth tend to identify youth with virtue, morality, and mental health. But to do so is to overlook the special youthful possibilities for viciousness, immorality, and psychopathology. Every time of human life, each level of development, has its characteristic vices and weaknesses, and youth is no exception. Youth is a stage, for example, when the potentials for zealotry and fanaticism, for reckless action in the name of the highest principles, for self-absorption, and for special arrogance are all at a peak. Furthermore, the fact that youth is a time of psychological change also means inevitably that it is a stage of constant recapitulation, reenactment, and reworking of the past. This reworking can rarely occur without real regression, whereby the buried past is reexperienced as present and, one

hopes, incorporated into it. Most youthful transformation occurs *through* brief or prolonged regression, which, however benignly it may eventually be resolved, constitutes part of the psychopathology of youth. And the special compulsions and inner states of youth—the euphoria of omnipotentiality and the dysphoria of estrangement, the hyperconsciousness of consciousness, the need for constant motion, and the terror of stasis—may generate youthful pathologies with a special virulence and obstinacy. In one sense those who have the luxury of a youth may be said to be "more developed" than those who do not have (or do not take) this opportunity. But no level of development and no stage of life should be identified either with virtue or with health.

Finally youth is not the same as the adoption of youthful causes, fashions, rhetoric, or postures. Especially in a time like our own, when youthful behavior is watched with ambivalent fascination by adults, the positions of youth become part of the cultural stock-in- trade. There thus develops the phenomenon of *pseudoyouth:* preadolescents, adolescents, and frustrated adults masquerade as youths, adopt youthful manners, and disguise (even to themselves) their real concerns by the use of youthful rhetoric. Many a contemporary adolescent, whether of college or high school age, finds it convenient to displace and express his battles with his parents in a pseudoyouthful railing at the injustices, oppression, and hypocrisy of the Establishment. And many an adult, unable to accept his years, may adopt

pseudoyouthful postures to express the despairs of his adulthood.

To differentiate between "real" and pseudoyouth is a tricky, subtle, and unrewarding enterprise. For, as I have earlier emphasized, the concept of youth as defined here is an ideal type, an abstraction from the concrete experience of many different individuals. Furthermore, given the unevenness of human development and the persistence throughout life of active remnants of earlier developmental levels, conflicts, and stages, no one can ever be said to be completely "in" one stage of life in all areas of behavior and at all times. No issue can ever be said to be finally "resolved"; no earlier conflict is completely "overcome." Any real person, even though on balance we may consider him a "youth," will also contain some persistent childishness, some not outgrown adolescence, and some precocious adulthood in his makeup. All we can say is that, for some, adolescent themes and levels of development are *relatively* outgrown, while adult concerns have not yet assumed full prominence. It is such people whom one might term "youths."

Social and Historical Implications

If the hypotheses stated in this essay are correct, we have experienced and will continue to witness a growth in the proportion of young men and women in their late teens and twenties who pass through that postadolescent stage I have called youth. If this be true, it will become the more important to

recognize the differences between adolescence, youth, and early adulthood, viewing youth as neither prolonged adolescents nor young adults who have not quite been able to navigate the passage to adulthood. Clearly these comments on youth will require further qualification and elaboration. We must examine in greater detail the way sociohistorical change enables more young people to enter a period of youth, yet at the same time defines for them the alternatives available during that stage of life. We must learn to identify the factors that make each of the characteristic transformations of youth more or less probable. And we must learn to understand and cope better with the hazards, disturbances, and pathologies that inhere in the possibility of youth.

The emergence of an ever larger proportion of young people who exhibit the characteristics of youth will also have important social, cultural, and political implications. I earlier suggested that throughout human history the great majority of men and women have been concrete in their cognitive functioning, conventional in their moral judgments, and dualistic in their views of truth. It can be argued that cultural, social, and political stability, along with the secure transmission of culture from one generation to the next, has required these psychological characteristics. If so, then the emergence of an ever larger group of nondualistic, postrelativistic, postconventional youths will have major effects upon all of those institutions, from the family to the churches, from the political system to the schools, that have traditionally been

charged with social stability and the transmission of culture.

Similarly that "cake of custom" that has, at a psychological level, bound societies together and insured their continuity may today be crumbling, with implications we begin to see in the sense of social and cultural malaise in all the industrially advanced nations. Psychological research suggests that, however widespread the ideal of the autonomous man and woman, this ideal has rarely if ever been historically actualized on a mass scale. It may be that modern conditions—the increase in cross- cultural contact, the age of affluence, the impact of the new media, the prolongation of education, the deferral of adult responsibilities, the rapidity of social change, and so on— are creating an ever larger minority (perhaps eventually a majority) of autonomous men and women. A society of such men and women would be vastly different from any we have known. It may not be too early to begin imagining how it could be a better society than ours.

Finally one established principle of cognitive psychology is that all individuals find it impossible to comprehend the mental processes of those whose cognitive development is much advanced beyond their own. For example, the conventional, law-and-order moralist described by Kohlberg finds it impossible really to understand autonomous, principled moral reasoning. Instead, he has no choice but to identify principled reasoning with the preconventional, egocentric, "anything goes" morality that he outgrew as

a child. A similar principle appears to hold in other sectors of development. For example, the concept of interpersonal mutuality, defined as care for another person because of his or her irreplaceable individuality, tends to be incomprehensible to people who can care only for those whom they consider like themselves. Those who are related to their parents through bonds of authoritarian submission will tend to confuse a three-dimensional relationship to parents with childish rebellion and disrespect.

The general principle that higher levels of development are incomprehensible to those who have not experienced them has important implications for therapists, as for others who deal with youth. It is, of course, possible to understand empathically many aspects of another's experience that one has not experienced oneself: a therapist need not have been psychotic himself in order to understand a patient who has been or is. Furthermore, the common complaint of youths that their therapists do not understand them is often a true transference reaction that must be traced back to earlier feelings about their parents.

But the possibility remains that, just as able and complex high school students are often misunderstood by teachers less able and less complex than themselves, so some youthful patients may encounter therapists who misunderstand their behavior and thought processes, confusing higher levels of functioning with regressions. Psychotherapeutic training armors the

therapist with powerful and often accurate ways of explaining away the patient's objections to his own interventions. In the end, however, the possibility remains that the patient may be right—that the therapist ma not only have failed to understand but be incapable of understanding. There is no sure-fire safeguard against this possibility. But we can at least hope that therapists themselves will be relatively "developed" human beings, that they will not automatically equate their inability to understand with pathology in their patients, and that they will view the therapeutic process not only as a way of helping someone else to grow but as a human experience in which they, too, may develop.

Notes

[1] Throughout this essay I assume some familiarity with the works of Erik Erikson, virtually all of which clarify the stage I term "youth." Portions of this essay were previously published in *The American Scholar.* The research on which it is based is supported by a grant from the Ford Foundation.

[2] Obviously interpersonal development, and specifically the development of relationships with peers, begins long before adolescence, starting with the "parallel play" observed at ages two to four and continuing through many stages to the preadolescent same-sex "chumship" described by Sullivan. But puberty in middle-class Western societies is accompanied by major cognitive changes that permit the early adolescent for the first time to develop hypothetical ideals of the possibilities of friendship and intimacy. The "search for a soul mate" of early adolescence is the first interpersonal stage built upon these new cognitive abilities.

[3] Research work with nonpatients suggests that the experiences I have termed "prepsychotic" are common among intellectual youth; that they are often precipitated by hallucinogenic drugs; and that they only occasionally lead to a truly psychotic episode.

Chapter 20

Occupational Difficulties in Adulthood

Cyril Sofer

Characteristics of Work in Advanced Industrial Societies

The occupational system of advanced industrial societies has certain structural features that appreciably distinguish the work experiences of most persons from those of persons in other types of society. These structural features present the worker with particular types of opportunities. At the same time they confront him with particular types of problems or constraints that affect the quality of his everyday work experiences and relations and the way in which his work fits in with the rest of his personal life and social experience. This chapter is concerned with the social structural sources of strain deriving from occupations.

Work is physically segregated from the home or local residential area. It takes place in a designated workplace to which the worker has to travel because of the concentration there of machines and materials juxtaposed

with each other in a planned set of arrangements; an appreciable part of his lifetime (for which no remuneration is received) may be consumed in the journey to work. There is typically little privacy in the work situation; the worker performs before a small "public" and is usually under continuous or intermittent surveillance designed to insure that he meets standards set by his superiors in the quantity and quality of his output. The work is subject to constraints of place, time, and standards set by others. The expression of strong emotion is discouraged. Work is a social activity in which the worker typically interacts with peers, superiors, and subordinates. These exert different types of pressure on him, sometimes conflicting with each other, and he has to manage these in a way that makes his behavior acceptable to all parties. He will be subject to particular pressures to subscribe to the norms of his immediate colleagues in regard to output and to an ideology that attaches special value to their contribution to their employing organization and to society. He must cope with the stresses of dependence and interpersonal conflict, while maintaining enough of his idiosyncratic approach to life to retain his sense of personal identity.

Most work takes place in large bureaucratic organizations. This means that it is done in the name of objectives not necessarily identical with the personal aims of employees; rationalistic means are used to achieve goals; persons are treated as resources available for pursuit of those goals; and subgoals are differentiated into specialized tasks to be performed by specified

departments. Tasks are assigned from the point of view of overall efficiency, not from that of the preferences of employees; creativity and innovation are the prerogatives of seniors; rewards tend to be of an extrinsic type (money, space, comfort), rather than being intrinsic to the performance of the task itself, and are related to observed contribution to the overall "organizational" task. Bureaucratic systems of organization facilitate the performance of large-scale tasks in mass societies, yield economic and social benefits from specialization and coordination, allocate work to employees systematically on the basis of qualifications, experience, and competence, and help to insure that favoritism and discrimination are minimized. They provide opportunities to many for self-fulfillment in an orderly and progressive career: for colleague- ship, training, advice, and mutual aid. But the ethic of rationalism places the individual at the disposal of his employers, whose requirements may well shift during his work life at points not coincidental with his own needs as these develop.

It is widely assumed or suggested that bureaucracy suppresses individuality. This view has been challenged by recent studies of 3,100 men representative of employees throughout the United States working in similar jobs. Taking organizational size and the number of formal levels of supervision as the main indices of bureaucracy, the results show that those in the more bureaucratic organizations were more likely to be open- minded and receptive to change and tended to value self-direction rather than

conformity. They spent their leisure in more intellectually demanding activities. These findings applied to both the public and private spheres of employment and to blue-collar as well as white- collar workers. The researcher attributes the results to three of the occupational effects of bureaucracy: the greater job security of persons working in such organizations, their higher incomes compared to men of similar educational levels, and the more complex jobs they do. At the same time he notes that bureaucracies provide especially close supervision of staff and that, having hired educated men and given them complex jobs to perform, they may fail to give them as much self-direction as their educational attainments and the needs of the work allow.

When blue-collar workers are considered on their own, smaller subunits are characterized by higher job satisfaction, lower absence rates, lower turnover rates, and fewer labor disputes. The explanation for this is probably that as organizations increase in size and tasks become more specialized, it is more difficult to maintain high cohesiveness or a level of communication felt as satisfactory. These findings do not necessarily imply that largeness of the overall organization in itself determines level of satisfaction, since one can assume, at least in some technologies, that the size of work groups can vary independently of this.

Workers do not choose randomly with respect to the type of firm they

join. Those who have a very strong economic orientation have been shown to work for very large companies, and those who emphasize noneconomic factors select the smaller ones. This type of differential selection leads to similar turnover rates in the two types of firms. A separate study of auto workers reports that the men deliberately gave priority to high economic returns at the understood cost of otherwise unrewarding and undemanding work. The majority said they would not be bothered by job changes that would move them away from their current colleagues. Nor did they look to their supervisors for social and psychological support in their work roles.

Large, complex organizations appear to have certain typical forms of psychological stress associated with their functioning. Although most persons, asked whether they would continue to work if this were not financially necessary for them, say they would continue to do so, those in large organizations are especially prone to say they would prefer to do so in a different job or to express significant reservations about what they are doing. Two major stress-producing conditions appear to be the role conflict and role ambiguity, and these appear largely as an outcome of employees' being required to cross organizational boundaries, to produce innovative solutions to nonroutine problems, and to take responsibility for the work of others. No doubt processes of social selection take place that increase the likelihood that persons who can handle or who enjoy conflict and ambiguity fill roles where these conditions are especially likely to occur. But however they are handled,

the endemic nature of these stressful conditions is incontrovertible. In a U.S. national survey of 725 persons representing that part of the labor force employed during the spring of 1961, about half the respondents reported that they were caught in the middle between two conflicting persons or factions: in 88 per cent of these cases at least one of the persons involved was an organizational superior of the respondent. Almost half of all respondents reported work overload, that is, conflict among tasks or problems in setting priorities. Four forms of ambiguity were reported as particularly troublesome: uncertainty about the way one's superior evaluates one's work, about opportunities for advancement, about scope for responsibility, and about the expectations of others regarding one's performance. The difficulties people had with their organizational roles increased as conflict and ambiguity increased. On the other hand, ambiguities in such areas can be worked into defensive attitudes and ideologies that function to protect self-esteem. In the study just described, personality dimensions mediated significantly the degree to which a given intensity of objective (situational) conflict was experienced as a strain by the respondent. The effects are also mediated by the helpfulness or otherwise of colleague relations. The authors distinguished between core problems located principally in the objective environment (on which they concentrated): mismatches between the requirements of a role and the capacities of the occupant; and difficulties that are primarily intrapsychic but are acted out in the work environment. But all these

intermesh, as core problems are succeeded or elaborated by derivative problems, that is, those created by the individual's attempts to cope with the core problem. Tensions arising from difficulties in work roles are not necessarily expressed wholly in those roles but may manifest themselves elsewhere in the total array of roles we all fill—as husband, father; sibling, friend, or citizen.

Intergroup conflict is a standing feature of work situations in contemporary society. Organizations are arenas of constant struggle between individuals and groups for status, power, resources, and higher shares of the collective output, in the course of which the parties seek to overcome, injure, neutralize, or eliminate their rivals. In relations between managements and workers, strikes are the most conspicuous examples of such conflicts, but they appear also in such less organized forms as work limitation, slowdowns, waste, labor turnover, absenteeism or, on the management side, overstrict discipline and discriminatory dismissals. While vertical conflicts between managements and workers arouse most public attention, this type of opposition is only one of many. What we conventionally call management is divided into a variety of subcategories and subgroups whose interests, outlook, and aspirations differ from and compete with each other. Nor are employees a homogeneous general class. They are divided into many varieties of occupation that struggle against each other for rewards, recognition, and precedence, just as many of them struggle against

management. In the large, modern, complex organizations a particularly prominent form of intergroup conflict is connected with division into groups of colleagues each responsible for a share of the work: the development of occupational identities based on life investment plays a key part in the acuteness of such conflicts. Conflict is typically contained in the work organizations of advanced industrial countries, rather than bursting out in its more destructive forms, because the parties usually have other overriding interests in common and because lines of cleavance are multiple, so that it is not in the interests of the parties to press any one division to its logical end.

Conflict can confer benefits on members of organizations and on those whom they serve by facilitating change, enabling alliances to be formed, providing groups with a sense of identity, bringing problems to the attention of higher authorities, clarifying expectation, correcting imbalances in reciprocity and power, mobilizing energy, clearing the air of simmering trouble, and allowing hostile impulses to be diverted outward. From a wide, societal point of view, conflict is not a pathological phenomenon to be understood as the desperate efforts of a deprived and discontented people, but a normal aspect of "antagonistic cooperation"[1] in a competitive society in which groups cooperate but at the same time use their power to influence the outcomes of that cooperation to their greater benefit.

At the same time conflict confronts groups and individuals with

breakdowns in their capacity to cooperate and to control their impulses, substitutes warfare as a motive or basis for association, blunts judgment about the behavior of oneself and others, encourages unrealistic beliefs and ideologies, reinforces self-doubt, provides a rationale for dishonesty or opportunism, and results for some in loss of power, esteem, income, or even employment. Even though structural forces and social processes provide the foundations or causes of conflicts, these tend to become personalized in the form of criticisms of the integrity, competence, and motivations of the individuals actively concerned. Since conflict is endemic in social life and inescapable in the organizational and occupational affairs of complex economic systems, it is a source of constant or intermittent stress in the work experience of most adults.

The individual's relationship with his organization appears partly to be replacing or displacing personal contacts. For many people that relationship comes to constitute one of the main sources of continuity in their life experience: while this can be argued to confer meaning and identity, there is clearly also a risk that people will become unduly dependent on their employing organizations and will play out on the organizational stage the strong emotions otherwise reserved for more private social relations.

The nature of work has changed appreciably during the past few decades. Physical tasks are increasingly being relegated to machines and

physical labor is being displaced by mental effort. The occupational skills of a person may have to change often during his lifetime or may become altogether outdated. Education and training, either formal or informal, are becoming continuing processes or matters of repeated injection/ application as work processes and systems change. Employers have become active in the educational and training process. Large employers are involved in a process of secondary socialization of their members: personality and identity are not formed once and for all in childhood, and at least their external manifestations continue to be actively reshaped in adulthood, largely through the deliberate efforts of employers.

With the rapid introduction of new technologies, certain older occupations disappear and new ones emerge, for example, those of systems analyst and computer programmer. This process reduces certainty in occupational planning, introducing new occupational routes less standardized or predictable than the old and increasing the diversity of alternatives. New dangers and risks in occupational investments accompany the creation of new opportunities.

The bureaucratization of work and the rapid introduction of new occupations and techniques have contributed to changes (and possibly tensions) in the relations of younger persons to older. The career arrangements of bureaucracies place the young (even those with the latest

technical skills) at the mercy of the older, putting the power to set norms and make decisions into the hands of the middle-aged.

Occupational roles have attached differences in social status, with professional workers and senior businessmen ranking at the top and unskilled manual occupations at the bottom. The higher the level of the occupation, the higher the morale of the person.

It is widely thought desirable to try to move up the occupational ladder, either during one's own lifetime (which is highly unusual) or from one's father's occupational status, and to help one's children move up from one's own occupation. Persons in a wide variety of occupational roles would prefer higher-status roles or may have aspired to higher-status roles that they have failed to achieve. Adaptation to such a situation, in the form of scaling down of ambition, can be expected in a large proportion of cases, partly because of the prevalence of this condition and the inevitable development of defensive ideologies that help to rationalize lack of achievement. But equally one can expect some less socially and personally "adjustive" reactions, such as deviant ways of gaining goals, retreat, or rebellion.

When comparisons were made of the mental health of men at different occupational levels, from white-collar workers through skilled workers, semiskilled workers, and low- level production workers, mental health was

found to vary consistently with level, with more problems reported at the lower levels. It is not altogether clear, however, how far this is a direct result of factory work (and therefore possibly transient) or how far a consequence of pre-job characteristics, such as low education and downward mobility, or of such factors as low income and poor housing.

Notes

[1] This phrase derives from W. G. Sumner.

Differences in Occupational Cultures

Probably the most important dividing line between social categories in Western society today is that between blue-collar workers and white-collar workers. These labels connote profound differences not only in occupational experience but also more generally in the quality of one's personal and social life, the opportunities one is likely to be able to make available to one's children, the values to which one adheres (including those involved in bringing up children), and the model of society that one holds.

The major factors that determine which occupational category a person will enter are the social class (largely occupational class) of his parents, the number of years of formal education he has had, the size of his family, and the attitudes of the family toward education. Of these factors the strongest is

one's own education, although the effects on one's progress of both education and social origin decrease in importance over time relatively to what has happened in one's career. Important handicaps to career advance are having a broken family (which affects both the husband and male offspring), having many siblings, or coming from a family not favorably disposed toward education.

Where mobility (either upward or downward) is appreciable, the mobile person experiences problems in his interpersonal relations and social identifications. Mobile persons are not liable to be closely integrated with persons either in their former or present social class in regard to life style and reciprocal influence. Mobile persons are more apt to be prejudiced against minorities and more apt to be preoccupied with their health; these attitudes may reasonably be interpreted as evidence of felt insecurity.

Intergenerational mobility is apt to create sharper discontinuities, particularly between the type of culture experienced in childhood and adulthood. Because of the increased importance of professionalism, educational selection divides children into separate educational streams with different occupational potentialities and consigns them to different social fates and life styles. When the children of professionals are not successful enough in their education to achieve the occupational level of their parents, participation in a different culture, possibly disvalued and probably more

localized, is their likely social destiny.

Blue-Collar Workers

Operatives

Persons who enter blue-collar occupations have not normally had a great deal of systematic vocational guidance and are not well equipped with information to help in their occupational choices, for instance, in estimating the probable fate of various industries. They tend to enter occupations yielding relatively high short-term earnings but having relatively little opportunity for further learning or scope for advancement. This is particularly important in view of the binding character of most early occupational commitments. Many of the requisite skills are acquired in the course of the work itself and are derived from immediate work colleagues: allegiance to the work group and adherence to group norms and standards of output become a necessary condition for learning and for pleasant or tolerable social relations while at work.

A good deal of the work of persons in this sector is simple, monotonous, or boring and may consist of repetitive operations on physical objects. It may offer little scope for affirming personal competence (in a way that gives the worker feedback on his effectiveness); tasks may not be closely related to

self-identity; and there may be little scope for achievement in the sense of recognition by others of the worth of one's contribution.

The context of the work may involve isolation from what is felt to be the heart of the organizational operation, a struggle to maintain or increase autonomy or control over working conditions, and effort to maintain and gain power vis-a-vis other occupational groups and particularly vis-a-vis managerial groups.

In an early industrial research classic, 180 representative workers were interviewed in their homes about their employment in one of the most modern automobile assembly lines in the world. Ninety percent of them expressed a dislike of the many jobs in the plant characterized by mechanical pacing and repetitiveness. A large number wanted jobs that lacked these characteristics. The mass production characteristic most disliked was mechanical pacing. Workers in unskilled jobs tended to devaluate themselves. The work often demanded "surface mental attention"; that is, it required a high degree of attention but was not intellectually demanding, thus being conducive to boredom. The research workers found that work arrangements denied to all but a few opportunities for a team relationship with other workers. Ability to interact was also limited by noise, speed of the line, and the amount of physical energy demanded.

The combination of the content and context of manual work is considered often to be alienating in that working conditions may foster powerlessness (the feeling that one is an object controlled and manipulated by others or by an impersonal system); self-estrangement (occupation is not experienced as constituting personal identity in an affirmative way); isolation (the feeling of being in, but not of, society, a sense of remoteness from the large social order, an absence of loyalty to intermediate collectivities); and meaninglessness (individual roles are not seen as fitting into a total system of goals of a group, organization, community, or society) .9

This is not a complete picture. There are many kinds of occupation and skill and varieties of working conditions in the blue-collar band. There is a large variety of technologies, each offering different opportunities for learning, effort, social relations, and satisfaction.

Workers of all grades have a great capacity for adapting themselves to the levels of satisfaction actually available in their jobs and for adapting even to the fact that few satisfactions (apart from income) may be available on the job and must be found elsewhere. In surveys relatively few describe themselves as acutely dissatisfied. Persons at the same occupational level vary widely in the extent to which their self-esteem is affected by the work they do; this depends on their relative investments in a wider range of human satisfactions.

Meaning can be introduced into jobs and job contexts found boring or unsatisfactory by those performing them. This is done, for example, by elaborating the movements required, by unofficial exchanges of duties between workers, by working to targets defined by the worker himself or by groups of workers, by introducing social rituals or games, or by thwarting supervisors and managerial groups. Colleagues often unwittingly collaborate with each other to use their relationships to express feelings and attitudes (both positive and negative) not strictly related to their work situation. Institutions can develop that act as defense mechanisms against tasks in a work system that arouse anxiety; an example is the depersonalization of patients, overelaborate division of labor, and ritualization of duties that occur in hospitals.

Persons in manual occupations grow up in subcultures in which expectations of satisfaction from work may not be high and the instrumental aspects of work are emphasized. Satisfaction with a particular job docs not depend purely on the quality of the work experience but on the relation between that experience, the expectations of the worker, and his assessment of the alternatives realistically open to him.

Once they have become established in their occupations the job aspirations of blue-collar workers arc typically not high, and their definitions of what constitutes success have to be judged by job needs as they perceive

them, that is, largely in terms of security of employment and reasonableness of hours, colleague- ship, and supervision. On these criteria blue- collar jobs have their own typical sources of anxiety and stress. Such jobs are less secure than others; the posts held by an individual typically are not related to each other in an orderly sequence; and earnings do not rise concurrently with increasing family needs, being related more to strength, skill, and speed than to the improvements in judgment, experience, or to the capacity for looking after others that is generally accepted to come with age. The industrial worker is more subject to occupational vicissitudes than persons in more skilled or senior posts; is likely to experience or perceive randomness in occupational success; is likely to fear machines and technological improvements for their possible effects on him; is not likely to see a close connection between ability, effort, and success; and is prone to develop a philosophy of life that attributes such success to luck, pull, discrimination, or the power of others in a better position to manipulate society. A distinct ideology of the underdog or underprivileged worker expresses hopelessness, resignation, and unwillingness to believe that one matters as much as other people and that one's needs and wishes will be taken into account.

In studies of the mental health of industrial workers it is reported that a large proportion suffer from "poor life adjustment." The mental health of these workers is reported to vary significantly with situational factors, chief among which is the opportunity that work offers for the use of their abilities

and for associated feelings of interest, sense of accomplishment, personal growth, and self-respect. Mental health is apparently also affected, though less appreciably, by financial stress; pace, intensity, and repetitiveness of work; the quality of supervision and personal relations on the job; opportunities for advancement and improved social status. Mental health is apt to be poorer where plants are large, a high proportion of employees are at a low level of education and skill, and personnel policies and services are below average. Mental health tends to be poorer as job level falls. Men performing routine semiskilled work experience general dissatisfaction, have a narrow range of spare-time activities, and have relatively little devotion to larger social purposes. Self-esteem is especially low in the less skilled.

In most advanced industrial countries a majority or substantial proportion of workers are affiliated to trade unions that seek to protect and advance their economic and related interests. The relationship of the individual with the union generally bulks larger as he comes to scale down his aspirations, settles for a steady job, and relies on the union to protect and advance his interests in the employment relationship and in competition with other occupational groups. In such cases the worker adjusts realistically to the fact that his mobility aspirations are more likely to be realized through his children. Ambivalence toward union membership and participation continues among those who remain ambitious to rise into the ranks of management.

The sheer size of modern industrial organizations combined with the existence of inevitably competing interests creates the occasion for the intervention of unions to deal with problems of disputes, fairness, and grievances; only in small firms it is possible to deal effectively with such matters through personal relationships. In their relations with unions, American workers appear to value most highly the job security and the protection from the dangers of wage reductions, arbitrary treatment, and deterioration of working conditions that they derive from membership.

American workers tend to have different expectations of the employer and the union. Acute conflicts in loyalty are most likely to occur in the organizing stage of unionism where ties of loyalty to the employer have to be broken for a union to be formed. In some cases the worker has little use for either employer or union, viewing both as evils to be tolerated and the whole work situation as unrewarding. But these workers appear to be greatly outnumbered in the United States by those who have no basic quarrel with the organization of industry and society and look to the union for a more equitable distribution of business income and for insurance against improper treatment.

Supervisors and Foremen

Supervisory positions have advantages over lower level jobs. Basic

wage rates are higher; earnings are more regular since they do not depend on hours worked per week; status is higher in both factory and community; and promotion is known to be generally on the shop floor from among equals on the basis of demonstrated merit.

At its highest this role has been described as mediation between the rigidities and impersonalities of command and the infinite varieties of human nature, and as safeguarding of individual human dignity. It is around the supervisor that the formal instrumental pressures of managerial systems and the informal "communal" aspects of shop floor work life have to mesh.

A review of empirical studies has shown that greater job satisfaction exists among supervisory personnel than among workers. In a research project all 55 production foremen in the same plant were interviewed. On the whole and in spite of rough times, difficulties, and frustrations, the foremen liked their jobs, their employing organization, their economic rewards, and the challenges of a dynamic work environment. But real dissatisfaction existed and real problems stemmed from the technical environment and the organization of work. The conveyor belt did not substitute mechanical compulsion for human supervision. It did not solve the foreman's major problems of maintaining quality and keeping the line manned. Combined with repetitiveness it created its own problems of adjustment and morale among subordinates. To be successful with his men the foreman had to absorb

pressure from many sources and still not become a symbol of pressure to his men. The foremen felt they needed help from their managements, and this was the main criterion for evaluating managerial colleagues. The foreman's main way of keeping up productivity was by keeping the line manned, but absenteeism (partly prompted by the assembly line) often frustrated this aim. The foreman was exposed to the fact that those who experience compulsions associated with "nonhuman" or "mechanical" methods are apt to accuse the agents of those compulsions of being inhuman themselves. The essence of the foreman's job was doing something different every minute.

Intermediate leaders are subject to different demands from above and below—typically demands for productivity (or its equivalent) from above and for human consideration from below—and hence are liable to actual or potential conflict in their behavior. In the U.S. Army during World War II, the noncommissioned officer was valued from above for "being a strong military leader" and from below for "being a good fellow." Ratings of foremen by superiors and subordinates have been found to be inversely correlated, with a tendency for those who are well thought of by one group to be badly thought of by the other. The supervisor must uphold the organizational standards while at the same time retaining the cooperative attitudes of subordinates. He is dependent on his subordinates both for his own reputation with his superiors and for the daily social interaction that makes work situations pleasurable or tolerable. If he does not collude with subordinates in

circumventing unpopular rules, his personal position may become untenable. The supervisor may have to choose between "riding" his men or being "ridden" by his own superiors; he has to carry heavy responsibility; he has to make decisions.

In the vertical information flow of the organization, he has to keep his superiors informed about what is going on without reporting in a way that brings criticisms upon either himself or his subordinates. He is likely to be by-passed by subordinates talking to other supervisors or to union representatives about what is going on in his section. The foreman acts as the work group's intermediary with parallel work groups as well as with intermediaries. Given the demand of subordinates for consideration, one can assume ambivalence in the attention of the foreman to external tasks. He operates in a context in which he is expected to get results, but the results of his section depend on the cooperativeness of his subordinates and the largely independent activities of senior colleagues whom he does not control.

As a consequence of increased specialization, the foreman is surrounded today by a dozen (other) bosses, each a technical or staff man who has taken away a different segment of what used to be the supervisory job.

The contemporary supervisor is expected to be knowledgeable about a

wide range of matters (including labor contracts and laws, company policy and regulations, technological processes, training methods) although he may well have come up the hard way and not have had much formal education. Nor may he be well prepared for the managerial side of his role: workers at the bottom of the corporate hierarchy learn to combat authority or to accept it, not how to exercise it or how to mediate between factions.

For the majority of supervisors little lies ahead in the way of promotion, since they do not possess the educational requisites for white-collar or managerial rank. Desk work may not in any case be attractive, or the entry into "polite society" may be embarrassing.

White-Collar Workers

Within the white-collar band new entrants experience some similar difficulties to blue-collar workers in occupational search and job establishment, although their vocational guidance facilities at school are almost certainly better. They have insufficient knowledge of what is involved in different occupations. They experience difficulty in estimating the prospects of different occupations, organizations, and industries. On the other hand, their preoccupations lie more with deciding what to do than with getting an acceptable job.

They may have to build a view of their capacities and occupational life

chances through a series of rejections at selection procedures. They spend an amount of time choosing between options that is disproportionate to the relatively small investment of time made in generating options. Anxiety to get settled, to be an accepted member of the world of work leads to premature job crystallization, often with subsequent regret as the binding character of early commitments is realized. But compared with blue-collar workers, white-collar and executive workers in bureaucracies enter well-defined channels, and their steps thereafter are prescribed, visible, well-regulated, and supervised. Executives are helped to develop in ways not normally available to other grades of workers.

Like blue-collar workers, the white-collar and executive occupational classes value security, continuity, interaction with others, autonomy, and duties that enable them to maintain and build self-respect, test and affirm their competence, and provide scope for achievement. Like these other categories, they are resources available to their senior management and experience the pressures of working to standards imposed by others. But they are usually able to take for granted the security, continuity, and adequacy of income that are problematic for the blue-collar man. Their problems lie rather in whether they can exercise a relatively high measure of autonomy, in whether their personal resources are being well used, or whether they can identify as their own and render visible to others the contributions they make to collective efforts in which the impact of any

individual is diffuse and hard to specify. Work tasks are more central to personal identity in this group, so that expectations from the work situation are high and dissatisfaction or frustration especially painful. The incorporation of work tasks into the self and a high measure of identification with the employing organization makes life satisfaction highly dependent on the work situation and career progress.

While the blue-collar worker has to tolerate the risk that he may be regarded as expendable in times of economic stringency, the white-collar worker has to tolerate a different form of insecurity and potential strain, namely, that flowing from high dependence on one employer. His skills are only partly technical but are also largely his expertise in the administrative and political processes of his own organization. A common situation is that the executive becomes heavily invested in, dependent on, and committed to one employer and is in a poor position to seek alternative employment should he experience strain or come to dislike his work situation.

Persons at higher occupational status levels report greater satisfaction with their work than those at lower levels; satisfaction seems to arise from the very fact of being in an occupation that ranks higher than others, and this has a halo effect on other aspects of the occupation and the work it involves. White- collar workers have higher expectations of their work and, in general, more sources of satisfaction. The executive and the professional have more

control than junior grades over their time, the pace at which they work, and their technological and social environment, and relative freedom from hierarchical authority, at least in the way of direct surveillance. They have the opportunities to extend themselves, to define or influence their roles in accordance with their capacities and inclinations, to exercise judgment in regard to priorities among tasks. Their work contributes to their self-esteem and can be integrated into their nonwork activities. This contrasts with the operative who may see no connection between what he does as a way of earning a living and what sort of person he is.

Executives and technical specialists at a wide range of levels have their needs for security and for social interaction met, but satisfactions in esteem, autonomy, and self-actualization increase as rank rises. Among equals in managerial rank the content of duties apparently matters: line managers report more satisfaction in their jobs than staff managers, especially in regard to esteem and self-actualization.''

Substantial differences exist between blue- collar and white-collar definitions of success. Emphasis on achievement in one's job and career appears particularly in nonmanual occupations, and emphasis on economic security appears particularly in manual occupations. Movement up the administrative hierarchy becomes in itself a criterion of success for the executive, a criterion whose significance is apparently maintained for a high

proportion of the work life even though objective opportunities for promotion actually decline.

Clerical Workers and Lower-Level Managers

The modern office and its staff are an outgrowth of large-scale industry. When industry was conducted on a small scale, offices were correspondingly small, there were relatively few office employees, they were appreciably better educated than blue-collar workers and in close contact with management. With the subsequent growth in size of organizations, in finance invested, in government controls and taxation of industry, in procedures for collecting personal taxes through employers, and in unionism, there has been a great growth of accountability, recording, and paper work. The numbers of office workers has increased greatly.

U.S. studies have emphasized that increased costs have led to the rationalization of office work and changed roles for the office worker. The roles of bookkeeper, clerk, and secretary have been fragmented, become more routinized and to some extent more mechanized—in this way following somewhat the same course as shop floor roles. Nevertheless, important differences exist in the connection of the duties of the office worker with abstract symbols rather than physical materials, in the clerk's physical proximity and access to members of the managerial hierarchy, in cleaner and

quieter physical working conditions, and in the opportunity to wear clothing also appropriate outside the workplace.

In regard to work satisfaction, one of the few exceptions to the rule that reported satisfaction decreases as level in the occupational pyramid lowers is that skilled manual workers are slightly more satisfied than rank-and-file white-collar workers. This is found in the United States, Germany, and the U.S.S.R.

Over the past few decades the salaries of U.S. office workers and blue-collar workers have converged, partly through rationalization of work, partly through wider educational opportunities, partly through the greater strength of blue-collar unions. Office workers seem to have been put in a position of status ambiguity, a difference arising between their status claims and aspirations, on the one hand, and their objective position and the reluctance of blue-collar workers to concede their superiority, on the other.

Strains among office workers and the lowest levels of management are thought to arise from salaries that are too low to finance the middle-class aspirations characteristic of these employees and from relative status decline. To the extent that office work becomes mechanized one can expect increasing strains similar to that experienced by the operative confronted with technological advances.

In Britain the basic skill of literacy used to set the clerk apart from the working man and give him a foothold on the lowest rung of the middle-class ladder. Although he lacked the income and security of the middle-class person, this is where his identification lay. Status considerations were powerful. But the connection with middle-class status has been altered by social and economic changes. Economic power has shifted toward organized labor and educated people have become less scarce. There has been a fall in the desirability and prestige of clerical work in the eyes of other occupational groups.

The clerk belongs neither to the middle class nor the working class. In social background, education, working conditions, proximity to authority, and opportunity for upward mobility, clerks in Britain can still perhaps claim a higher status than most manual workers. But using other criteria such as income and skill, they may be rated lower, or no different, by manual workers. Clerical workers are also divided among themselves or uncertain on the question of where they stand in the social hierarchy.

The position of clerical workers and lower- level managers has recently been particularly affected by the introduction of electronic data processing. Persons in these grades have tended to be especially security-minded, and many have worked under conditions more stable than those of either blue-collar workers or executives. The disorganization and reorganization

associated with change to EDP may have found them less ready in personality and experience to meet the demands for adjustment. The nature of clerical jobs is changing with the automation of office processes. The most routine jobs are being eliminated and work pace is becoming more closely tied to machines, so that absence and lateness matter more. While the office worker still has more freedom than the blue-collar worker to leave his workplace or to vary his production level, more specific work quotas have been imposed. Opportunities for promotion may have been somewhat reduced, and some shift work has been introduced. There is lower tolerance for errors, which become transmitted far through the system and are more visible to superiors and customers. With the rationalization of the work system, each job gains significance in the continuity of the overall process and the individual becomes more accountable for his actions. With automation a proportion of jobs may be eliminated or changed radically. While new jobs are created, the persons displaced may not be able to fill them or may not be easily amenable to retraining.

In a British study drawing on data from nine firms that had introduced computers, it was found that this and concomitant reorganization were experienced as a threat to staff security. There was much initial anxiety, even where little redundancy ensued. Staff often had to be redeployed. It proved difficult to avoid reducing the status and salary of staff in the 45 to 55 age group, particularly if they had held supervisory positions. In the clerical area

there was a greater concentration of responsibility and a need for more staff of high intelligence: those associated with running computers had to be able to master complicated new skills. In some firms junior managerial roles also changed, sometimes only eliminating routine, but in other cases involving transfers from reduced departments and loss of status. Not all the results of the new computer installations were negative. Many of the younger clerical workers were attracted toward machine work, which seemed to promise greater interest and more promotion opportunities than the "elementary" clerical duties they were performing.

Middle-Level Managers

A review of empirical studies has shown that median satisfaction with jobs is higher for managerial than nonmanagerial personnel and that satisfaction increases with echelon level within management.

The middle manager's work is carried out in a highly "political" context; he is part of a constant struggle for relative power, autonomy, and influence over the way the overall enterprise is run, not only between individuals, but also between departments and occupational groups. The acuteness of these struggles derives largely from the investments made by the persons involved in their occupational training and experience and from the difficulty of radical occupational shifts in adulthood— particularly among those wishing to

protect their status as higher-level managers or technical specialists.

The middle-level manager's situation is deeply affected by expectations (both his own and others) that he should climb up the administrative hierarchy. He has two tasks to perform simultaneously: that of carrying out organizational tasks in cooperation with colleagues and that of facilitating his upward rise. Most organizational tasks are carried out by groups that develop solidarity, shared definitions of their mission and status, and shared conceptions of how they should relate to other task groups, subordinates, and superiors. Therefore, the individual must be an acceptable colleague on easy terms with equals, prepared to give credit to their contributions and to refrain from pressing his own claims to special consideration and merit. But if he is to advance it is also necessary that he differentiate himself from his peers and convey his potential ability to distance himself enough to view their organizational contribution objectively or, if required, to control it from a position of greater authority. Both task performance and career building make high demands on interpersonal competence. Discussion of this topic usually emphasizes the need for the executive to conform, to represent himself as similar to others. But the task is more correctly viewed as a wider form of self-management, involving both a measure of conformity and a capacity for discreet and acceptable differentiation.

The character of a great deal of executive work is diffuse and is not

subject to clear-cut criteria of adequacy. This makes assessment of the executive's competence dependent on evaluation by colleagues, of which evaluation by seniors is the most crucial. Because of the absence of objective evidence of performance and the difficulty, where there is an ascertainable output, of establishing that it is a direct consequence of a particular executive's input, evaluation of the executive tends to acquire a personal quality, so that he gets evaluated on such grounds as enthusiasm, confidence, assertiveness, patience, and cooperativeness alongside technical competence, knowledge, and capacity for problem solving. The personal component of this evaluation is accentuated by the fact that appraisal by superiors covers not only his performance but also his potential: an aspect that necessarily brings into issue the amount of flexibility and capacity for growth and change in his personality relative to the more senior roles in the organization. It is common practice for large organizations to inform their executives in appraisal interviews of their personal strengths and weaknesses in relation to their careers; the rationale is that this will increase the likelihood that the person will alter in a direction likely to bring greater organizational rewards, with resultant benefits to both the employer and himself. The extent of defensiveness in appraisees and the protective distortions that occur imply that the interviews are stressful events at least for the appraisee and possibly tor the appraiser also. The executive faces a unique life situation in that he cannot escape or by-pass an organizational mirror that confronts him with

the image held of him by his most important seniors.

He is commonly subject to personal dependence on one or more sponsors, persons with whom he has an interdependent relationship of reciprocal support. The executive's career becomes linked with that of his sponsor or sponsors, increasing his chances of rising as his sponsor gains status and influence, but simultaneously increasing his vulnerability as his sponsor's career goes through its own vicissitudes.

A systematic connection between rank, conflict, and tension has been found in a national survey, with the maximum of conflict occurring at the upper-middle levels of management. The research workers interpret this as partly a consequence of the still unfulfilled mobility aspirations of middle management, in contrast with the better actualized aspirations of top management. The greatest pressure is evidently directed to a person from others who are in the same department as himself, who are his superiors in a hierarchy and who are sufficiently dependent on his performance to care about his adequacy without being so completely dependent as to be inhibited in making their demands known.

The tapering of the administrative hierarchy and the definition of success as movement combine to produce career disappointment in many executives. Some adapt fairly comfortably to their work situation or are

helped to do so by the personnel institutions of their organizations. The disappointed person may be able to call on his individual defense mechanisms in the sense that he can tell himself that he has not been given a fair chance or that he would not stoop to the methods used by others to secure advancement. He is commonly helped by the existence of shared group ideologies, developed with colleagues in the same position as himself, whose central theme is that personal merit is not the main determinant of success. Some are able to find compensations in other aspects of their lives. External compensatory roles may include devotion (or more devotion) to familial, recreational, political, or social service pursuits. Role segmentation may usefully insulate compartments of one's life against failure and disappointment in others. One form of (negative) response is to turn "sour" in relations with the employing organization by withdrawing enthusiasm, good will, and vitality from one's work role, complying with the formal requirements of the role but withdrawing identification from it.

A key factor in career disappointment is that persons come to base their self-identity on the assumption that they will in due course come to occupy certain organizational roles more senior than their own. A career disappointment can then come to constitute a disturbance in self-conception, involving the necessity to reassess or reclassify oneself, and an embarrassing withdrawal of the image of the prospective self that one may have held out to intimates. Seniors may be felt to have betrayed one. Personal and familial

sacrifices may have been made in the vain pursuit of illusory occupational goals. Internal readjustment may be painful, and in seeking to justify to those closest to him his revised expectations and evaluations, the person may have to perform a stressful about-face and express himself in transparent rationalizations.

Technical Specialists

Line managers report themselves to be more satisfied in their jobs than staff managers, mainly because the latter feel they have to be directed by others.

Technical specialists complain that they are subjected to administrative routines and controls that are alien to their notions of reciprocal control by equals; that they are overconstrained by considerations of practicality and profitability and have too little opportunity for work of long-term importance; that undue secrecy is placed on their work, on relations with colleagues in other organizations, and on publication; that they are appraised and managed by nonspecialists who do not understand their work; and that their rewards and promotion chances are inferior to those of line administrators. A distinction has been drawn between cosmopolitans and locals: this differentiates persons whose major commitment is toward their discipline and to colleagues wherever they are located from those whose

more abiding interests and personal loyalty reside with their employing organization. While important conflicts no doubt exist, most people are unlikely to lie at one extreme or another.

Accommodative mechanisms arise or are developed to reduce strain, to forestall and to settle actual or incipient conflict. In general, bureaucratic organizations are adapting themselves to the high proportion of technical specialists they now employ. Special roles are created for specialists in segregated departments, for example, research and development. Special administrative arrangements can be made to allow for colleague control in project teams whose leadership shifts in accordance with the dominant specialty involved. Specialist leaders are appointed who have qualifications and interests in both the disciplines involved and in "organizational" needs, and who can mediate between the technical specialists and superiors. Leave can be arranged to provide sufficient contact with outside colleagues. Dual career ladders have sometimes been created so that specialists can improve their prestige, income, and facilities without giving up their specialties. Those people who are most insistent on pure science and academic freedom are apt to avoid careers in the applied research departments of large organizations. Even in the most enthusiastic and tenacious research, worker compromise and adaptation will occur.

Industrial research provides appropriate positions for those technical

specialists (who may be a substantial proportion) who are distinctly interested in their subject and feel it is an important part of their lives, but who are unwilling to have it as the dominating factor in their lives.

Some studies have concentrated on the organizational scientists who remain anxious to retain their full status as members of the scientific profession. They have to span two areas, since consolidation of their organizational positions is a prerequisite for gaining and maintaining recognition by external colleagues. Only a positive evaluation of their own work by their organizational superiors will give them the facilities and resources they need for successful research. At the same time they become dependent on having assistants and subordinates who become counters in their own career success.

Senior Administrators

Taking various dimensions of job satisfaction separately, a review of U.S. research shows that within management security and social affiliation needs are equally met, but that the needs for esteem, autonomy, and self-actualization are better met at each higher level. The phenomenon of greater job satisfaction at higher levels of management is not confined to the United States; in a cross-cultural investigation of managerial attitudes in 14 countries, higher levels of management on the whole reported that their

needs were better satisfied in their jobs.

Seniors are more exposed and vulnerable to criticism than middle-level executives or blue-collar workers. The less senior members of an organization are better protected by the narrower specification of their responsibilities and are in a better position to discharge their obligations by adhering to the instructions issued to them. Their errors are usually less visible and their rights more likely to be defended by formal collective associations or their informal equivalent.

Senior administrators may experience frustrations from the limits to their behavior set by the crystallization of organizational practices over time by laws, regulations, and agreements covering the roles involved in the organization, the means by which these must be filled or vacated, and the conditions under which personnel may be employed or dismissed.

While it is one of the tasks of the senior administrative group to initiate changes, such changes are liable to alter the existing distribution of power and prestige. A tension can be set up between following out the logic of an organizational change and accepting the implications that the change will have for one's own position and behavior.

In the earlier phases of his career the senior administrator will probably first have developed and practiced some form of specialist expertise, then

have combined this with responsibility for a group of subordinates. At the most senior levels opportunities for direct development and practice of such special knowledge decrease, and usually the transition has to be made to being a generalist. The security of acknowledged specialist knowledge and techniques is given up for the exercise of judgment and wisdom on issues on which there is no clear-cut right and wrong and where one is more exposed to challenge.

The senior administrator has to steer a path between the advice of a variety of rival specialist colleagues. He has to show that he respects the views of each but may, nevertheless, have to act in ways that advance the interests of some and obstruct those of others. In order to maintain objectivity in his judgments he will find it necessary to maintain distance from previously close colleagues, with probable feelings of isolation or loneliness. His wife may also find herself in a similar position in relation to the families of her husband's colleagues. The administrator carries responsibility for large sums of money, large numbers of people, and far-reaching decisions but does so in a chronic state of uncertainty, since knowledge of the relevant facts, including future events, is always imperfect.

The roles that senior administrators play at the top of an organization have more scope for variation and for idiosyncratic interpretation than those lower down. This is largely because it is the function of the senior executive

person or executive group to define organizational priorities. If, as is usual in large organizations, a number of people are involved, either formally or informally, some accommodation must take place between them in regard to relative power and duties. How things turn out will clearly depend on a combination of formal position, personality, traditions of colleagueship and popular support among subordinates and, perhaps, sponsors and shareholders. Interpersonal relations with close colleagues will bulk very large in the psychological life space. There will be a further division of labor in the psychological sense that each senior administrator will tend to perform particular psychological functions or have these projected on to him by subordinates. One might, for instance, symbolize instrumental purposes, another the supportive "maintenance" activities that also appear necessary in organizational functioning. A study of a hospital has identified the allocation of these roles among a colleague group of three and implied that, apart from objective task definition, problems may arise if administrators fit poorly into the psychological functions allocated to them by group processes, if they are too similar in personality, or if their own prior socialization has prepared them inadequately for these highly demanding social psychological roles.

Chapter 21

Marriage and Marital Problems

Ian Alger

Introduction

Whatever its origins in various civilizations throughout recorded history, and whatever the joys and anguishes it may bring, the fact that in our society marriage is the goal, both striven for and achieved, of the overwhelming majority of people insures it a high place in the hierarchy of "normal" maturational goals. At the beginning it should be made clear that this chapter intends to deal with marriage at this current time in history, and more specifically with middle-class American marriages. This narrowing of focus is being undertaken because this type of marriage is the one about which most clinical psychiatric experience has been accumulated and, indeed, is the one about which over 90 percent of the psychiatric literature is written. This is not to say that marriages in other classes of our society, among minority groups of various racial and ethnic backgrounds are not relevant and important. It is to say, however, that knowledge about them comes from a

sociological and anthropological base, that even this knowledge is only gradually being developed with any completeness as survey and statistical studies improve, and that these marriages are by and large not the ones that have found referrals to psychiatrists.

Just as types of marriage other than the middle-class variety exist in our society, different types of marriage exist in other cultures and societies, not only now, but also back through history. Again no major focus will be placed on these other varieties, except to underline the point that the institution of marriage is by no means universal in its characteristics, but differs from class to class, in different societies, and at different periods of history in the same societies.

The organization of institutions in a society can be explained on the basis of providing for the needs of that society and its people, and these needs can be described as biological and social. For example, needs for food, shelter, and sexual experience and needs for security, companionship, and child nurture may be seen as expressions of pure biological necessities, or pure social necessities, or in some instances a combination of both. The institution of marriage, depending on the details of its organization in any particular instance, can be seen as meeting necessities such as child care, companionship and security, and sexual fulfillment. One theory explains the differentiation of the primal horde on the basis of sexual jealousy, which

resulted in the males claiming the right to their own females. Will Durant suggests another theory when he writes, "Some powerful economic motives must have favored the evolution of marriage. In all probability (for again we must remind ourselves how little we really know of origins) these motives were connected with the rising institutions of property. Individual marriage came through the desire of the male to have cheap slaves, and to avoid bequeathing his property to other men's children."

This theme finds an echo in the demands of today's women liberationists who call for equality and freedom from the enslavement of marriages in which women are treated as property. Leaving aside for the time a discussion of the merits of this argument, it would seem true that marriage, especially as it becomes a legal contract, has great influence in the way in which power and wealth can be accumulated and then passed in a very discriminatory fashion from one generation to the next. Powerful families arrange marriages with other powerful families, and a king in one realm marries a princess from another. Monogamous marriage, with its nuclear organization, preserves and stabilizes the social organization and also provides for a continuity through one generation and on into the next. Thus, not only is power and property preserved, but also religious beliefs and social position, which, in turn, tend to preserve the economic and political structure of the society.

With this introduction let us turn to an examination of marriage as it exists in middle-class America today.

The Marriage System

Marriage—The Majority Choice

Nearly all of us grew up in a family, in a nuclear family if you will. And although our experiences may have varied greatly, those many of us who experienced pain in that growing up, and who saw the frequent despair and anguish of our parents, nevertheless join with the large majority of our fellows and, despite any earlier protestations to the contrary, get married. But the tendency to marry is even more impressive than that. Over the past 40 years the divorce rate in this country, and not alone in this country, has risen markedly.[1] In the past decade the rate has shown another increase. Yet most of those who have divorced remarry, and, indeed, contrary to earlier hypotheses, the majority of those in second marriages claim that they have found greater satisfaction and happiness than in their first.[2] Thus, since 1940 for every unit of increase in the proportion of the population divorced, there have been five units of increase in the proportion married (p. v).

Therefore, the almost inevitable route for an individual in our society is to become married, or to put it another way, to join a marriage system.

Becoming a member of a marriage system is no small undertaking, for while it can be entered into fairly readily, the implications are enormous "from that moment on." These implications involve not only the relationship between the two partners but also possibly myriad responsibilities to the larger society and to associate members of the marriage system, such as children, the couples' own parents, other relatives and assorted in-laws, and occasional friends. Furthermore, these responsibilities, at times cause for joy, at other times merely liabilities, may begin in random and erratic ways from the moment of the wedding vow and continue until the system closes with death or makes a transition into the system of divorce.

Society has always made entering the marriage system easier than leaving it. This commitment by the two partners holds both the promise of satisfaction in a close relationship with another human being through a continuity of mutual experience and the possibility of entrapment and disillusioned agony through a process of mutual erosion. We want to examine and understand this institution of marriage as we also look at the problems that arise in relationship to it, and while we then consider what therapies and remedies are, or may become, available to ease the suffering.

Why the Choice Is Made

Among other things marriage has been labeled an "institution," but I

have chosen to talk of it as a "system" because I want to imply the features of change and dynamism, of interrelationships within the marriage and between the marriage system and other systems in the society. In addition, I wish to include the concept of the system existing and changing in time as other systems in the world also alter in time and relationship. When marriage is considered under this concept of flux, the impossibility of defining "marriage" becomes instantly apparent. Let us pursue the idea of the "marriage system" a little further, then. In this system two main partners voluntarily enter a relationship that actually is licensed, or certified, by the authority of society and that thereby becomes, whatever else it may be, a legal contractual agreement. The contract makes a demand, rare even in ordinary promises, much less legal vows, that each partner shall promise to love the other as long as both shall live. The impossibility of anyone's having sufficient control over feelings to make this promise realistically has, of course, been commonly recognized; and although for centuries hapless couples remained miserably together, the easing brought about by recent divorce legislation now removes the eternity from the promise and opens the option of certain release from such impossibly burdensome emotional obligation. However, rarely at the moment of making the vows do the parties to the contract consider the future shadow it may cast. Rather, they are more often eager and desirous of publicly declaring their affection and love for one another, and they look forward to the happiness that can come from the growing together of two

people who care for each other, who share much with each other, and who long to share more. They anticipate the unique human fulfillment that can come from the intimacy of a physical and spiritual continuity of closeness between a man and a woman. In such hopes are found one of the basic forces that make marriage so appealing. Loneliness is an unhappy feeling, and although in one sense we must all exist alone, in another sense we all seek companionship. We developed our very humanness in this sharing of experience with others, with our own parents and those who reared and cared for us as infants and children. As we live we seek the constant renewal of that humanity in this sharing. For those who grew up deprived of this kind of human contact and love, relationships with others may be anticipated with anxiety and defensiveness. Still others may have grown up with such self-mistrust and low self-esteem that they continue to seek a chronically infantile dependency on others. More will be said later of the problems these and other developmental deprivations and distorting experiences can create in the marriage system. For the moment, however, let us emphasize again the compelling attractiveness of this anticipated future of love growing in a dyadic closeness.

In addition to this appeal, the marriage system also offers the couple the sanction of having their own children and moving from the role of children themselves to that of mother and father. Indeed, in these days when young people so often easily live together with no formal marriage vows, it is the

wish to have children legitimated in society's eyes that leads many of them, if not to the altar, then to the desk of the county clerk. From another perspective the desire to legitimate the child premaritally conceived is the most telling motive in many teen-age marriages that are statistically most likely to end in early divorce.[3]

If the desire for children motivates the origin of many marriage systems, then the presence of the children binds the marriage more tenaciously than any other factor. Children conceived in love so often become the main reason for continuing the marriage when the love is gone. Although love for the children may often be a telling factor in one parent's decision not to leave, it is also true that the children can serve as a convenient rationalization for those who fear to move on in their lives. Some partners have become so dependent on the marriage for realistic or emotional reasons that they dare not attempt to make a life apart from their current marriage, feeling that such an effort would be doomed to failure.

A third reason for marriage has a less lofty tone, but nevertheless resounds with practicality. If suburbia has little to offer for single people, the rural climes have less, and urbanity notwithstanding, the big city can be a very lonely place as well. In other words, the larger society is compatible with the marriage system, and one might even surmise that the two were made for each other. It seems evident that coupled living is favored by all kinds of other

systems in the society, from the income tax to the double occupancy. Two may not be able to live as cheaply as one, but in our society the establishment of a marriage system with two major partners is encouraged on every hand. [4]

A fourth reason for marriage has been deliberately left to last, not because it plays no part, but because it plays a diminishing role in the deliberation preceding marriage. It is the factor of sexual fulfillment. With the widespread availability of reliable and easy methods of oral contraception, and with all the other changed conditions that permit young people an easy and early intimate association, sexual experience before marriage has become more and more the usual course, and marriage is more rarely hurried along on the wings of intense but frustrated lust. One might think that with increasingly liberal sexual attitudes and expanding sexual freedom the importance of romantic love as a central force in mate choice and marriage would diminish. But romantic love is actually not that closely associated with sex itself; rather, it grew from the eleventh- and twelfth-century courtly games of idealizing the "loved" one beyond all reality, and in the haze of daydreaming ecstasy imagining a life of superb joy lived in idyllic wonderment and delight in a never ending transcendence of rapture. The myth of this impossibility spilled from the chambers of the court, beyond the aristocracy, and today the romanticism floods our lives, given special propulsion by the power of multimedia advertising. The promise of perpetual

youthful glow, of poised and promising breast, of never fading allure sweeps through the airwaves and drowns us in a commercial gush. But still the seductive promise of a life of everlasting love, of the one and only, falsely leads the multitude to anticipate the continual glow of warmth and closeness. Alas, the romanticism has a short half-life, and the hopes of one who has depended on the idealized romanticized image of his beloved are soon shattered by the day-to-day realities with which the marriage system has to engage.

Who Is Chosen

From considering why people choose to enter a marriage system, let us continue our exploration by looking at the partners people actually choose. In cultures where families arrange marriages the considerations are clear. Economic and social advantages play a large part, and if love grows between the marriage partners, all well and good. Of course, in our own society many marriages are still arranged, although the details of the arranging are often kept obscure. Nevertheless, marriage within the same class not only is common but is given much support, especially in the upper class, and when this tradition is broken, wills are frequently changed and the details of trust funds altered so that the passage of wealth and power can be controlled and channeled. It is true that in this country considerable marriage across vertical class lines take place, and certainly the trend to upward mobility favors this

kind of intermarriage. In spite of this, however, and in spite of the apparently democratic idea of the freedom to marry the person one loves, the great majority of marriages occur between partners who share common cultural, ethnic, racial, and educational backgrounds.[5] For example 99.8 percent of white spouses are married to white spouses, and 99 percent of black spouses are married to black spouses. The least crossing of class occurs in the upper and politically powerful classes where the largest stakes in terms of money and power are in jeopardy. Royalty and the upper classes have always been keenly aware of the importance of marriage in maneuvers of political power, and although they have always had more sexual liberty and freedom of relationships than the rest of the population, they have been scrupulously careful in the way marriage contracts have stipulated the ownership and inheritance of property. Undoubtedly much of the age-old concern for women's chaste behavior has grown from men's fears that their worldly gains would be inherited by another man's children. This consideration, of course, has relevance to the status of women, to the esteem in which women are or are not held as persons; it will be explored further in the section dealing with the nature of the relationship between the partners in the marriage system and with the burgeoning women's liberation movement.

Reference was made to marriage across vertical class lines, but horizontal mobility is also an important factor in our current culture that affects not only the mate choice but also the quality of married and family life

that develops. Large proportions of our population move every year, often to new areas thousands of miles away from the old home. With this constant shifting, kinship systems have greater difficulty maintaining any meaningful relationships, and the new marriage system, when it is established, must begin to function often with very little outside support from the families of either partner. Although many attributes of such newly formed couples may lie within narrow and similar boundaries, such as educational level, race, and religion, many other features may be quite unfamiliar, having to do, for example, with local customs, verbal and nonverbal communication patterns, and even general life outlook.

Mate choice may also be influenced by personal manipulative factors, such as marrying the boss's daughter or marrying a doctor or lawyer. And only the diehard romanticists would say that such marriages could not succeed. Although that sought after quality of close intimacy may be lacking, unions based on these self-serving yet solid motivations may endure and fulfill the lives of those so united in many ways. Other reasons for mate choice may fall into an increasingly neurotic category and be related more to the personal distortions and inadequacies of one or both of the partners than to cultural or other forces in the general social system. An immature person, for example, may seek a new family haven in a marriage at the point where other demands that may be experienced as terrifying are presented. Rather than go to work or continue in college, a young person may see marriage as a way to

avoid the anxiety these other routes may evoke. If a boy or girl is insecure and frightened of social venturing, the offer of a sinecure may be overwhelmingly attractive. In a society where a woman's value as a marriage partner is distortedly based on her physical appearance and her sexual coefficient, many young women still caught in the trap of such a dehumanizing attitude may actually decide to accept a marriage proposal "now when there is a chance" rather than wait, because to most waiting may mean waiting forever, and to many in our culture this seems like a fate worse than married death.

The basis of neurotic attraction may be even more closely tied to the intimate interactions between the two people involved. Many very comfortable arrangements work out between people who have vividly disparate characteristics. By no means is the attraction of opposites to be construed as neurotic in itself. Rather, the delight and stimulation, the excitement and adventure, the peace and comfort that can come from such intermingling of differences make for more richness in life's experiences. However, cases where the differences fulfill neurotic patterns—although they may create temporarily stable arrangements that allow greater freedom for both partners in the marriage system—may also result in vulnerable linkages that will be least able to withstand stresses of living. Then the individuals involved may not be able to adapt by themselves to a new life in which more independence is required.

Functioning in the Marriage System

All factors notwithstanding, the marriage system is entered into. Those who have the temerity to give advice may say that it should not be undertaken too young, and yet not too late, that marriage is best undertaken between those of different natures, and yet between those of the same background. Statistics show some convincing data on the marriages that have some better chance of surviving,[6] but other critics might question whether survival of a marriage is any valid criterion of its worthwhileness. It would seem that when it comes to a specific case the task of advising a couple whether to marry is most difficult. What makes the prognosis even more uncertain is the very fact that marriage is a system and will evolve in relationship to all the other world and life forces; thus, the mass of factors affecting the prediction lie mostly in the future and beyond the grasp of the most skilled analysts or readers of fortunes.

Once the system is established it has a most complex evolution, indeed. The course will be different depending on how old the partners are; what is their economic underpinning; whether it is a first, second, or third marriage; whether there are auxiliary members of the system at the start, such as children from earlier marriages or relatives who will be living in the same household. Obviously I cannot undertake consideration here of every possible combination of circumstances. To begin with, then, let us consider some of the

challenges and situations that must be met by a newly formed marriage system in a somewhat uncomplicated setting with no auxiliary members of the system as yet.

The Newly Formed System

Earlier mention was made of the existential truth that in one sense each of us is alone in this life. And yet in another sense we are never alone, and our way of life can never be understood except in a social context, in relationship to others. In each system of which we are a member, we have a usual role or series of roles, and our social beings are defined by this multiplicity of roles. Our individuality, therefore, expresses itself in the number and complexity of roles we have in different contexts or systems. A sense of self, or person, runs through all the roles, but the role self is no less real because the behavior changes from role to role. The idea that in marriage "two become one" has a romantic beauty, but a practical pitfall. The individual who grew from a child in a family was part of that family system. But as he grew he joined other systems at school, in social groups, and at work. As he developed he usually organized less and less of his life in conjunction with the family system, and, indeed, he often had formed a separate existence in several ways by the time he was ready to enter marriage. The marriage system as a rule requires a more stringent "togetherness" than any other system, even the primary family. From being an individual involved in many systems, one suddenly

merges in the identity of a "couple," and it is in the constricting implications of this coupling that the narrowness of many marriages begins to pinch. Of course, the renowned honeymoon period may so counter the disadvantages in the coupling system that weeks or months (or occasionally years) may pass with the spouses so involved in the pleasure of their relationship together, and with the possibilities of growth contained within it, that the limitations are not experienced as such. The newly formed system has much pleasure and challenge to offer. Since close living will be one of the hallmarks, there is a continuing communication on a verbal and nonverbal level, both in awareness and beyond awareness, during which basic rules of living are established. The intricacy is such that rules must evolve about who makes rules, and in this way hierarchies are established in different areas. Such achievements are necessary for an orderly existence that is not always brewing anxiety in its confusion. Perhaps no area is more important for the establishment of a tolerable and workable marriage system than this one of communication. Greene has noted in his categorization of problems most often brought to the counselor that problems in communication now rank first.

In the early period of the marriage, in addition to establishing modes and rules of communication, the couple also may be enjoying an opportunity for experience together, with just the two of them, that may be very sweet and quite rare in their previous experience. It is true that the trend now,

especially in cities, is for joint living before marriage; as a result this kind of close personal living experience, together with working out some of the practical problems of living, occurs before the formality of marriage vows. An advantage of these informal arrangements is that one person may live with several different partners; thereby he learns that the experience can be very different with different people, and yet that some of the living situations that develop have to do specifically with the necessities deriving from the situation itself, and not from the particular people in it.

In the early stages of the marriage there are also many new and exciting tasks that can best be accomplished by the two working together, and from this kind of joint effort a good deal of satisfaction is inevitable. Usually a new living quarter is needed, which must be furnished.[7] Beyond this all the chores and everyday jobs must be accomplished, and with the development of the communication patterns, agreements and contracts are developed for handling these things. In the economic area agreements must also be made, either openly or covertly, about the patterns of earning, buying, and saving that will develop in the particular marriage system. Two people from similar backgrounds and having similar outlook will have less difficulty reaching agreement on such practical issues. Agreement, of course, also depends on the creation of adequate communication, and factors other than background determine this, varying from personal communication style, to personal prejudice, to neurotic or double-binding communication experience in the

past.

The "Couple" Identity

Although the honeymoon period can be happy, productive, and very important in laying the basis for important patterns to be followed as the marriage continues, there still is the potential for much trouble deriving from the consideration of the individuals in the system as a "couple." The veneer of enchantment in being known as "that nice couple" can wear very thin. It may be true that entering a marriage system does not necessarily mean closing down other possibilities for personal growth, and, indeed, the thesis that marriage *need* not mean this will be pursued later in the chapter; but the experience of a multitude of married persons has been that entering the marriage system has meant embarking on a voyage down an increasingly constricted tunnel, chained by love and obligation that eventually erode to hate and resentful duty. The reasons for the erosion may actually relate less to the closeness than to the isolation that is so often associated with it. And the reasons for the isolation vary in each marriage system, yet may stem from personal characteristics, from the nature of the marriage system itself, or from the context of the larger society.

Reference has already been made to our highly mobile population; this mobility not only breaks up kinship systems but also disrupts friendship

systems, so that no longer do groups of people easily maintain friendships over many years. When a family is going to live for a few years at most in one community, and then be relocated on the other side of the country for the next few years, the tendency to develop a self-sufficiency as a closed system is encouraged. In high-rise apartments families are often engulfed and overwhelmed by sheer closeness and numbers, and in the midst of the crowd become more isolated rather than less. Paradoxically as space is squeezed, and community areas for recreation and even local shopping where friends can meet are eliminated, families are increasingly isolated in their living arrangements. This is true as well in the suburbs where neighbors may live next to one another for years and yet never meet or even speak for more than a superficial exchange. Again the isolation is the key, with the resulting turning in. A further factor is work for members of the family. Places of employment may be far from the place where one lives. If both husband and wife work they may travel in different directions. This could lead to an independence that one would think might counter the effects of the too great closeness. But if both must return to be together after work, the advantages of the separateness cannot be exploited, and the strings of the marriage "bag" may be drawn more closely and tightly.

Each couple's marriage system is only one in a virtual sea of such relationships. The pressure, therefore, is to stay within each narrow system, not only because of factors in that particular marriage, but also because if one

partner would like to move out more freely, he or she may find no welcoming for this, since the multitude of others are sequestered in their own togetherness. Social events tend to be organized for singles or for couples. Both partners in a marriage system are usually invited out for dinner, to a party, or to the theater. If independent activities are included, they most often are organized along sexually segregated lines, such as women's card groups or men's bowling clubs. If sexually mixed activities are sanctioned they most often are related to some specific task, such as educational classes, parent-teachers associations, political clubs, and the like. From these examples one can see that opportunities for one individual to develop himself or herself in a separate direction are to some degree available in spite of social pressures favoring couple togetherness.

The greater pressure, however, may come from within the structure of the marriage system itself, for in such a closed system expectations are set up that work against individual spontaneity and that tend to regulate the lives of the people in the system. Since so much of life is approached from the need to work in the system mutually, compromises are made and each partner tends to gear his life more and more in relationship to the other. Thus, if the wife is working during the day and taking classes for a degree some evenings, expectations will be set for the times she should be through and ready to spend time with her husband. Since he may have arranged his time to meet her after class, her option of making arrangements with someone later is

limited. To expand this example, the pressure of expectation and accountability that can develop is enormous. In addition to the social and system aspects of the closeness, personal characteristics must also be considered. One of the most insidiously destructive forces in a marriage system is the neurotic dependency that develops and, indeed, is fostered by the very way in which the system now operates. To be cherished, loved, and cared for by another person is truly a wonderful experience. To be able to turn to another person for help and to find them dependable in their concern for you is also a most gratifying human experience. But to define, especially unconsciously, your own value in terms of the way another human being behaves in relation to you is to be not only personally underdeveloped in self-esteem and maturity but also tremendously vulnerable to hurt. The corollary is that this neurotic dependency on another for one's own sense of self leads to excessive demands on the other person that disregard the other's own individuality and personal integrity and attempt to control the other person. The aftermath of such relating is a deluge of resentment, frustration, constriction, and possibly depression or rage.

In brief, then, a marriage in which the partners are free to grow as individuals and to relate themselves to other systems in a full and human way is not much encouraged by the nature of our society, is handicapped by the ubiquitous marriage system as it now exists, and is virtually impossible in any marriage system where either partner is personally so insecure that he

operates in a neurotically dependent way, opposing the growth and expansion of his spouse as well as the development of himself.

Women in the System

The particular place of women in our society must be considered here, because it plays such a crucial part in the marriage systems that are developed, and also because it is being challenged anew with a vigor that already has shown results. That women have been discriminated against as a group seems beyond dispute. Documentation of the extent of the discrimination is easily found, and only relatively recently have women even begun to have equal rights under the law in civic matters as basic as the right to vote. But the effects of the discrimination are so widespread and so universal that the lives of women in our society are adversely affected either directly or indirectly every day in every place where women are to be found —the home, the school, work, the arts. In spite of revolutionary efforts on the part of women's rights advocates, there is a remarkable persistence of the conviction that a woman's place is in the home, that a girl should be raised primarily to be a good wife and mother, and that, indeed, if this does not continue the very institution of the home and family will be undermined and the future of the country itself placed in jeopardy. Raising a girl to believe that her basic goal is to become capable of attracting a man who will then marry her may make it almost impossible for her to achieve her full potential as an

individual person in her own right. When such tremendous emphasis is placed on physical attributes, as is done in our culture, effectively forcing the woman into an image of a plasticized sex object, the damage to dignity and personality is likely to be extensive. A further crushing bind is placed on the girl when the idea is insinuated that to the extent she develops herself as a person and shows herself to be intelligent and capable she will be running the danger of engendering competitive and hostile feelings from threatened men, who will then relegate her to the role of a "castrating woman" and thereby diminish her chances of finding relationships with interesting men and eventually forming a marriage relationship. The poignancy of this problem can be no better illustrated than to note the incredible fact that in a test involving the completion of a story about a student who placed first in a medical school graduating class, the women being tested, more often than not, saw this honor as a disadvantage when the first place student was a woman; in contrast, when the top student was a man, the distinction only heralded a future of continuing benefits.

Not only does the denigration of women as people have stifling effects on the growth of a maturing girl, but also the deleterious effects continue throughout the marriage and eventually lead to intense resentments and possibly tragedies. The superior attitude of men fosters an atmosphere of competition and lack of equality that breeds chronic domestic warfare and alienation. In the later stages of marriage the woman is often more hopelessly

trapped in an intolerable life because she lacks the grounding that could enable her to develop her own individuality and find a new and independent, if not separate, existence for herself. If the attitudes discussed encourage a battle of the sexes, small wonder that it is over sex that many of the battles are fought. Again it must be noted that many in the younger generation today have moved a long distance from the attitudes described. With the acceptance of equality between men and women has come the recognition of women's right to enjoy their own sexuality with the same freedom traditionally accorded to men, both married and single. Modern contraception has provided much more freedom for women, and liberalized abortion laws, such as the one passed in 1971 in New York, has added further social sanction to the new sexual and personal independence of women. As women truly are given more equality, their degraded position as sexual objects loses relevance, and sexuality between men and women will also express their mutual humanity, and not be "the" prize either taken, or withheld, or proffered.

Early Phases of the System

In our review of the marriage system we have considered the newly married and some aspects of the way in which the partners develop rules of cooperative behavior and communication systems, as well as some of the tasks and goals related to this phase of their lives. Often both may work while one or both continue in school, and a period of adaptation ensues. Divorce is

frequent at this early stage, especially in those who marry young. Probably the young have not each developed sufficiently as individual persons to allow a contract that has much likelihood of endurance. Before long, the growth in both partners may be such that disparities develop that can never be bridged. This, together with the adventuresomeness and energy of youth and the more liberal attitudes to divorce already present in our society, makes it more understandable why the rate of divorce among the very young is so high.

For those who enter the marriage system and do not soon leave it for divorce, the next important phase may be that of childbearing and childrearing.[8] Although more mothers continue to work after the birth of a child, and although day-care centers are being established at an increasing rate, a large majority of mothers stay home during the years when the children are young. The advent of children makes a drastic change in the system, for while a marriage system remains, a family system is now established; and even though the marriage system can end by death or divorce, the family system does not, and the members of that system (mother, father, and siblings, plus all the extended family members) continue in their family relationships as long as they live. Children, let it be said again, profoundly affect the marriage system. If the system was locked in before, the ties that bind are now vastly multiplied. Responsibility for the children tie the parents to each other as well as to the children, and the love and affection for the children create some of the strongest bonds and devotion known. Not

only do children raise the cohesion coefficient, but also they alter the intimacy factor in the marriage system. Earlier we mentioned that the close intimacy in the marriage often resulted in an isolation and alienation of the partners from other relationships. With children added to the system not only is the former isolation from others still present, but now the closeness between the husband and wife is encroached upon. Intimate times are difficult logistically, and when they are finally arranged the husband and wife (now also father and mother) may have little energy and incentive left. Such are the joys of parenthood.

The mother more often than not bears the brunt of the added work and strain at home, while the father increasingly becomes aware of his new financial responsibilities. The importance of maintaining and even increasing his income binds him further not only into his family situation but also into his work situation. Such phases in development are often referred to euphemistically as "learning the realities of life." The fact that marriage systems are organized as separate units contributes to the strain because sharing the tasks is difficult, and the continual yet often trivial chores are not relieved, even by the relatives, the aunts, grandmothers, and sisters who used to be available when the family was a larger conglomeration of generations. Wives often grow depressed, and withdraw from relationships with their husbands. The sexual relationship may be adversely affected, especially if it is experienced as a duty and an exploitation. During this period men are more

likely to seek relationships with other women as relief from the tedium at home with its incessant demands and frequent sexual rebuff.

Stresses on the System

As we continue to examine the flow of the dynamics in the marriage system, we can see how the relationship between the man and woman fluctuates in response to a multiplicity of factors both in their own personal growth and in the marital situation, which, in turn, is affected by forces in the larger society as well as by the addition of children. When stress threatens to disrupt the system, adaptational changes are necessary, or the dysfunction engendered will be manifested in unusual behavior or symptoms in one or more members of the system, or in some unusual function of the entire system. Gross disruption of the system would include one member leaving the system entirely, or the collapse of one member, such as hospitalization, or violence among the members. Stress may be applied by forces outside the marriage system itself. For example, the husband may lose his job, not as a result of personal incompetence, but rather as a result of overall economic recession in the society. Or severe illness may strike a child or the mother and require a mobilization of all other family members, with a reallocation of priorities and a major shifting of emphasis in everyone's lives. The children's development brings a series of crisis points, and these can be moments when the adaptational capacity of the family may be sorely tested. On the other

hand, at such moments of stress the family has the greatest challenge and opportunity for growth, and each member of the family system may have a new occasion to redefine goals and relationships, so that not only may the family continue as a more integrated and successfully functioning system, but also each individual might have an enlarged personal capacity.

The problems that children bring in infancy and early childhood are often the source of much tension because the parents are aware of the literal helplessness of the youngsters, and therefore feel especially keenly the responsibility that falls on them as adults. In later childhood school and peer problems are often the focus of family stress. Then as adolescence approaches and the children increasingly move in their own directions and challenge the authorities at home and at school, a whole new series of tensions must be met that take on a more social aspect and that break into the insularity of the family. Here again a paradox is seen, because in our society family life has been constricted as many of the functions formerly undertaken in the family, such as education and recreation, are more and more being performed by other systems in the society. Education in schools now includes sex and family life, while the education brought into the homes through television completely overwhelms the attempts in many families to create some special and unique direction for that particular family. The tensions that began as children neared adolescence burst into clear-cut warfare among teenagers and parents in many families, and the alliances and blame thrown back and

forth may stir a turbulence that rocks the foundations of the family and the marriage. At those critical points—infancy and early childhood, preadolescence, and the teenage years—the stresses in the family may become so severe that counseling or psychiatric help is sought. When family therapy is sought the issue most often resolves back to the marriage system, and the family adaptation is strengthened when the marital partners can redefine their goals and relationship and then cooperate in managing ways to meet the demands and responsibilities of the growing family, while at the same time not being engulfed to the extent that no life as individuals, or as man and woman, is available.

As a family grows the economic burden usually increases as well, and if college education is included in the children's future the economic strain and the sacrifice demanded may be quite severe. But assuming that a family manages to hold together through these stages, a new and most critical point in the marriage system is in the offing. At the time when the children have reached the point where they are more and more responsible for themselves, and certainly by the time some or all of the children are either in college or are working for themselves, the focus inevitably begins to turn again to the marriage relationship and to the fate of each of the two individuals in that relationship.

Middle Phases of the System

For the woman in many families, moments of personal decision may have been experienced when it was planned to begin a family, when the youngest child entered school, leaving more of the day free for other activities, when children reached their teens and were able to provide more care for themselves, and then when most of the children were old enough to leave home. At such moments of decision, many women resume earlier employment; some mothers may go back to teaching when their own children are in school, and others may reenter jobs in business. Other women, who had always wanted to further their education, begin to take courses, perhaps on a part-time basis, and a large number of women in their late twenties and early thirties become very aware that unless they begin to make progress in their own development they may not have the opportunity later, for it will be too late.

For these reasons, among others, many women reach a point of crucial decision in their thirties, when they review the lives they are living, and consider whether any changes may be possible. At this point women may feel that if they are ever going to make a change in their marital situation they would best do it now, for their youthfulness is still reflected in their appearance and their energy, and the possibility of establishing a new marriage is still a realistic one. In addition, many women now feel that an unmarried life provides greater possibilities of satisfaction than a married one, and so the fear of this different life style is not nearly as intimidating as it

once was, nor is the social stigma of divorce and a single life nearly so powerful, or likely to be incurred.

At this time the husband may feel more pressure to increase his income, and many men may take on an extra job, or work overtime, or undertake further education in the evening. In addition, owing to the competitive business atmosphere, many men until the age of forty are engaged in an intensive struggle to reach a position of some strength and stability, because after forty further significant advancement will be unlikely, and the pattern for the future of the employment career will be fairly well settled. On this somewhat different timetable, men may experience their time of crisis between forty and forty-five, when they realize that this is their last chance for a major change in life style. At this point many men form new relationships with younger women and experience a resurgence of youthful feeling, with the desire to live through many of the fantasies that they may have suppressed in their adolescence. In a sense a second adolescence may emerge, with the feeling that if the home, in this case the home of the secondary family, is not left at this time, the future will be closed, and the old life will continue until true death brings an end. At this time many men also make rather radical changes in career, or at the least make a major shift within the same field, possibly involving a geographical move as well.

In some instances a third possibility is chosen, when both husband and

wife are able to change together and evolve a very new kind of life for themselves. When this does not occur, and when the resolution does not result in a continuation of the old life pattern, divorce ensues, and friends may wonder at the dissolution of an apparently successful marriage of over twenty years' duration. However, the real surprise may be that the divorced individuals often are infused with a new excitement, and that both may go on to experience happier and more fulfilled lives. The course of the marriage, it would seem apparent, has to do not only with the external realities of children and finances but also with the intrinsic strengths of the marriage partners as independent individuals. This theme, then, keeps repeating itself; namely, that a crucial factor in determining the course of a marriage, as well as determining what happens after divorce, is the degree of personal individuation and personal security and development of each partner.

Later Phases in the System

When the marriage system continues after the critical period of middle age, new goals emerge. The possibility of more leisure time together may bring new enjoyment into the lives of the couple. The loss of friends becomes more common, and the facts of aging and death are increasingly evident. Illness may have been experienced before, but now the certainty is that illness and decline will be more and more an inevitable part of the agenda. Often families established by children may be a large source of interest and delight,

but again the tendency for the breakup of the closer kinship systems in modern America affects the intensity of such relationships, so many older people may have to adjust themselves to distance and infrequent visiting. Although more affluent older people may be able to establish retirement ways of life, large numbers of the population are left increasingly to their own resources, which usually are meager; with their failing health and the inadequacy of publicly supported programs, many are doomed to an increasingly isolated and frighteningly lonely existence. The dependence of the married couple upon each other becomes more crucial and necessary than ever. It can be the source of tremendous resentment, as well as of severe anxiety, for roles of who will be dependent on whom may suddenly, after a lifetime, forcibly be reversed. Goldfarb has noted that the crux of most marital problems in older people is their handling of dependency relationships.

Changing the System

Intrinsic Factors

In the discussion so far, we have explored some of the features of the marriage system. We have considered reasons why people may join the system, factors influential in the choice of a partner, problems in establishing a workable system, and an overall view of the goals and difficulties present at different stages in the evolution of life as the marriage system attempts to

provide a workable arrangement for its members within the intertwining matrix of all the other systems in the society. At this point let us examine more closely certain intrinsic factors in the traditional system that reflect both its strengths and its shortcomings, and particularly let us examine the relationship of the individual in the marriage to the system itself, to himself, and to the larger world.

Monogamous marriage contains within it a dilemma, because the flourishing of love, which is one of its top priority goals, is discouraged by all the features that coerce and demand allegiance and affection. Compulsion breeds rebellion and resentment; duty and obligation discourage spontaneity and delight. Love cannot be forced by legal decree and formal contract, any more than it is engendered by blame or guilt. Thus, all the arrangements, formal and informal, that insure the binding of the marriage and that are justified by the necessity of protecting property rights, and the social good of preserving stable family situations for the nurturing and rearing of children, serve at the same time to entrap the partners in the marriage and provide a soil hostile to the development of mutual affection and love. The commitment sanctified in the promise to forsake all others becomes instead a captivity, and the added irony is that the spouse who promised to love now hosts a growing resentment, and at the same time through his own vow has cut himself off from the love of those he has forsaken. Nor in this system of values is much thought given to the pain of those who are forsaken.

The problem facing the individual partner in the marriage system is to establish a modus vivendi permitting his own and his partner's individual growth without jeopardizing the possibilities for an intimate relationship together; at the same time he must assure a cooperative and mutually respectful endeavor to meet all the housekeeping and other maintenance necessities, and fulfill, in addition, the requirements and obligations to children and members of the community at large. This task is almost too much to expect from any individual, particularly in a system that puts so many barriers in the way.

Cuber and Harroff undertook an in-depth interview survey of 211 middle-class married people, and from the detailed reports concluded that there were five main marriage arrangements. The classification was based on the interview material of people whose marriages had lasted ten years or more and who said that they had never seriously considered divorce or separation. The first type is the "conflict-habituated." In this relationship there is considerable tension, although it is usually controlled. "There is private acknowledgment by both husband and wife as a rule that incompatibility is pervasive, that conflict is ever potential, and that an atmosphere of tension permeates the togetherness." The authors note that some psychiatrists have speculated that the deep need to do psychological battle with one another constitutes the cohesive factor insuring the continuity of the marriage.

The second type of relationship is described as "devitalized." The authors write, "These people usually characterize themselves as having been 'deeply in love' during the early years, as having spent a great deal of time together, having enjoyed sex, and most importantly of all, having had a close identification with one another. The present picture ... is in clear contrast—little time is spent together, sexual relationships are far less satisfying ... and interests and activities are not shared." Further comment is made that this type of "duty" relationship in marriage is very common, and that those in it often judge that "marriage is like this—except for a few oddballs or pretenders who claim otherwise."

The third described type is the "passive-congenial," which is much like the devitalized, except that the passivity pervading the association has been there from the start, giving the devitalized at least a more exciting set of memories. The authors speculate, "The passive-congenial life style fits societal needs quite well also, and this is an important consideration. The man of practical affairs, in business, government service, or the professions, quite obviously needs 'to have things peaceful at home' and to have a minimum of distractions as he pursues his important work. He may feel both love and gratitude toward the wife who fits this mode."

The fourth category is in extreme contrast to the first three and is called the "vital" relationship. The essence of it is that the mates are intensely bound

together psychologically in important life matters. As one of the interviewed subjects said, "The things we do together aren't fun intrinsically—the ecstasy comes from being *together in the doing."* The authors elaborate, "They find their central satisfaction in the life they live with and through each other—all else is subordinate and secondary."

The final type outlined is the "total" relationship, which is described as like the vital with "the important addition that it is multifaceted ... in some cases all the important life foci are vitally shared." Both these last two types are described as rare, both in marriage and out.

From the description of these five main types, it can be seen that factors other than the individual personality characteristics of the partners played an important part in the style of marriage arrangement. Relationships outside the marriage, whether these included sexual involvement or not, play a significant part in the lives of many people. The restriction of freedom of relationship can be the single most eroding factor in the marriage system. By having the freedom to develop other relationships, and to engage in activities with other people, a marriage partner can pursue his or her own development in a way that is not possible if most activities are restricted to those engaged in with one's marriage partner. Possibly one of the most destructive demands in the covert marriage contract is that which encourages the belief that one person can supply another person's needs in every area. A

man or woman in this framework is expected to be a companion, a friend, an intellectual equal, a lover, a helper, a parent, a sharer in interests in sports, and on and on and on. No one person can meet the needs of another in all these ways, and, indeed, no one may be able to satisfy another fully in any one of these areas.

If the marriage system were not threatened by the inclusion of other people, it seems possible that much enrichment would then be made available for each of the partners. In turn, as each flourished with the addition of this new stimulation, he or she would return to the marriage relationship renewed and with more to offer the partner. In this light the idea grows that loving one person increases ones' capacity to love others, and that love is not diminished by the inclusion of others. In practice, however, the inclusion of other relationships frequently does threaten the marital relationship, and probably for this reason so many of these outside relationships are carried on clandestinely. This, in turn, poses a dilemma for many, who feel uncomfortable with this double role and who therefore suffer guilt and anxiety. As a result they either have periodic unsatisfying "flings," or live with a burdened feeling of uneasiness, or eventually break the doubleness by breaking the marriage, or by giving up the double life and settling for a more drab and unsatisfying continuity in their marriage.

Therapeutic Approaches

In a discussion of marital therapy, the first focus should be on the problems. In the chapter so far, problems in living of almost every sort have been discussed. Within the definition of the marriage system, it is evident that any problem that affects any individual in the system, or in the expanded family system, or any situation that influences the effective functioning of the marriage system can be considered a problem related to the marriage. In a sense, though, this means that almost every human problem can be seen as a problem related to marriage and the family. Indeed, there is much to commend this point of view. With the development of general systems theory and theories of communication, the idea that any human behavior can be understood outside the context of its occurrence has lost ground. The increasing expansion of family theory and family therapy is a clear-cut application of these newer theories to actual clinical problems. More and more frequently, when an individual, be he a child, or the adult in a marriage or in a larger family system, is found exhibiting behavior that could be labeled "symptomatic," or in behaving in a disruptive manner, that particular "identified patient" is understood by clinicians as a member of a system, and his behavior is understood in the light of the behavior of those around him, and in the particular context of his living. So it is, more specifically, that when one member of a marital partnership has behavioral or symptomatic disturbances, the context of the marriage itself is now frequently included in the therapeutic effort. Some clinicians have defined family therapy, of which

marriage therapy is a variety, as a method for treating the family, as opposed to treating the individual. However, Haley, a pioneer in the field of family therapy, has noted that the concept of family therapy is inclusive and operates even when a single member of a family system is treated by a therapist. He makes the point that no one participant in a system can be influenced in his behavior without that influence having an effect on all other parts of the system. Briefly, then, he holds that family therapy is all that *has* ever been practiced, although often the practitioners were themselves unaware that this was the case.

Before continuing with any further discussion of therapy, let us return for the moment to a further appraisal of the problems. Leaving aside those behaviors that appear in individuals, such as depressions, acute psychotic episodes, anxiety states, alcoholism, and various behavior disorders, let us consider the complaints that overtly can be related to the marriage system and in fact are presented as such. Greene has provided a recent listing of the major reasons couples give when they appeal for professional help with their marriages. Based on the responses of 750 couples, the survey shows that the most frequent complaint now is lack of communication. The next eleven specific marital complaints, in order of frequency, are constant arguments, unfulfilled emotional needs, sexual dissatisfaction, financial disagreements, in-law trouble, infidelity, conflicts about children, domineering spouse, suspicious spouse, alcoholism, and, finally, physical attack.

These, then, are the leading reasons why partners in marriage seek counsel and therapy. Since we have tried to look at marriage as a system, it would be consistent to consider the marriage therapist as a consultant to that system. This is possibly a different way to consider the role of the psychiatrist, but it has some advantages. For one, the therapist is not placed in the position of having to be a saving influence. Rather, the initiative is clearly left with the partners, who come to an expert for appraisal and consultation, who may be able to gain some further understanding of the reasons for the dysfunction of their system, and who may also take suggestions and advice from the consultant and in an experimental mode try out various new possibilities. In light of the previous discussion on the factors affecting the system at various moments in its evolution, one can see that the consultant would attempt to evaluate the strengths and weaknesses of the particular system, in terms of its members and of the supporting systems interacting with it, and he would further attempt to understand the nature of the stresses being applied in both general and specific ways. With this kind of background information he might then suggest various ways in which new operations in the system could be implemented, or in which certain tasks formerly attempted by the system might be given less important priority or abandoned altogether. For example, perhaps grandmother need only be visited once a year, or possibly one partner might cut down on committee activities in a local political club. Again, the consultant might suggest that

problems in the way the two partners were communicating might be contributing to massive misunderstandings; by helping with the analysis and correction of such problems, the consultant may contribute to a new level of cooperation and satisfaction. In another problem area the consultant may provide direct help with sexual difficulties, utilizing approaches formulated by Masters and Johnson—if not directly himself, then through referral to therapists trained in such methods.

Without further specific examples, it can be seen how the marriage therapist can act as consultant to the marriage system; and by considering the multitude of factors present in the system, and by utilizing his own special training and skills, he can engage the partners in their own therapeutic endeavor.

There is still a difference in approach among those who will see only the couple, those who will see only one of the partners, those who will see both partners, but only in separate sessions, and those who will vary their approach and see at times one, at others times both, and at other times each in separate sessions. Perhaps some of the confusion can be resolved by realizing that different systems are involved. Each individual is in essence a system in himself, but never *only* a system in himself. The individual always relates to other people, and he relates to people in many different systems, such as his marriage system, his friendship systems, his work system, his

community system, and so on. The dilemma for the therapist develops if he must choose between the individuality of the single patient or the continuity of functioning of one of the systems of which the patient is a participant member. This pivotal choice becomes the therapist's moment of truth, for it is at this juncture that he reveals himself as one who believes in the freedom of the individual to choose his own destiny, or as one who believes that the needs and merits of the particular system override those of any particular member, and thereby allies himself as therapist-facilitator to the continuation of the existing system.

Other Directions

In their struggle for growth people move in many different directions, make many false starts and return to start over again, and often never are able to achieve the growth they would like. A couple may seek marriage therapy, but find as they explore the possibilities that one or both do not want to continue either the therapy or the marriage. The variations are many. One or both may then enter therapy by themselves, to continue in the marriage or to break it. They may begin individual therapy and then combine again for marriage therapy. It is also important to realize that people in a marriage system have many other possibilities than therapy. Some, of course, stay stifled in a continuing unhappy and unproductive system. Some seek divorce. Only some seek therapy, which, as has been noted, may eventuate in several

possible outcomes. More recently others have been seeking new styles of life that attempt to make over the old marriage system entirely. Some have moved toward communal living. Others have experimented with group marriage. Others have tried to break some of the constrictions in regular marriage by becoming "swingers," combining affairs and other relationships in an open contract with mutual participation.

The divorce rate, and the amount of unfulfillment and unhappiness in marriages that continue, together with the increasing attempts by so many of our younger generation to find new possibilities for relationship, leads to the conclusion that at this time in history the traditional marriage system is having great problems in effectively fulfilling many of its stated functions. Nevertheless, the system does not seem about to disappear; it is so intimately related to the basic structure of other systems in the total society that nothing short of a complete social revolution would lead to its early disappearance and replacement. Therefore, the continuing need for marriage therapists, or consultants, is apparent. Possibly the traditional system can continue to evolve. Perhaps the most promising hope lies in the direction of more openness in the system, of greater freedom for the individuals in the system to develop independently, while yet retaining the core cooperative relationship of intimacy and continuity. In the fostering of this evolution, it is hoped that the consultant-therapist can make a significant and helpful contribution.

Notes

[1] Rates of final divorce decrees granted under civil law per 1,000 population: United States, 1932, 1.3; 1945, 3-5; 1960, 2.2; 1965, 2.5; France, 1932, 0.5; 1945, 0.6; 1950, 0.9; 1960, 0.7; Sweden, 1932, 0.4; 1945, 1.0; 1955, 1.2; 1960, 0.9; 1965, 1.2. Divorce rate per 1,000 married couples: United States, 1935, 7.8; 1964, 10.7; France, 1935, 2.3; 1963, 2.9; Sweden, 1934, 2.3; 1962, 5.0 (pp. 29, 31)

[2] A very large proportion of the marriages that are dissolved within less than 20 years are followed by remarriages. For example, in 1960 over four-fifths of the white men who had first married some 18 years previously and had been divorced had remarried. The remarriage rate of nonwhite men was nearly as high; the corresponding rate for white women was seven- tenths, and that for nonwhite women was about five-eighths (p. 400).

[3] The divorce rates per 1,000 married persons, from four selected states having rates available, 1960-61: the total divorce rate for men under twenty was 24.8, and for women 29.0 (p. 57).

[4] A great deal more is known about the divorced population than the separated ... at the time of the 1960 census, over 2 million were separated and over 3 million were divorced. (p. 222).

About 2.7 million men in 1967 were bachelors (statistically 35 years old or over who have never married), and 2.8 million women were spinsters (statistically 30 years old and over who have never married). (p. 298).

[5] Among couples who married during the 1950's and were still in their first marriages in 1960, the median educational attainment was 12.3 years for both husbands and wives.

About three-fourths of the married couples in the United States in 1960 comprised a husband and wife of the same national origin. English-speaking and German persons of foreign stock had high rates of outmarriage to persons of other origins including native Americans, whereas those of Polish, Russian, and Italian foreign stock— with a higher proportion of first-generation Americans—had lower rates of outmarriage.

Persons of Russian foreign stock very rarely married persons of Irish or Italian foreign stock.

A cross section of married Protestants and Roman Catholic adults in the United States have a similar moderate amount of intermarriage; married Jewish adults have relatively little religious intermarriage by comparison with the levels for the other two groups.

The 1960 census showed that only 0.4 percent of United States married couples had a different race reported for husband or wife (pp. 391-394).

[6] In 1960 rates of dissolution were highest for those who married in their teens and lowest for those who married in their twenties. Persons with marriages "not intact" included the separated as well as the divorced and the widowed; among these persons the proportion of nonwhites was about twice as high as that for whites. The percentage of adults who were divorced was smaller among the foreign born than among the second generation.

The Northeast had by far the lowest percentage divorced. The West had uniformly the highest percentage divorced. The rural areas generally had the lowest percentage divorced and separated, and the large cities had the highest.

Well-educated white men had a much lower percentage of divorces than the less educated. The relationship was more complex for non white men; the percentage divorced rose irregularly as education increased to the level of entrance into college and then fell as education increased further. Likewise among women, rising education up

through the early college years was associated with a rising divorce rate; although the percentage of divorces was lower for college graduates, it reached its highest level for women with graduate school training.

Occupations in which especially small proportions of divorced men were found in 1960 included accountants, college professors, draftsmen, physicians, and high school teachers. Corresponding occupations for women included librarians, music teachers, and elementary and high school teachers (pp. 400-403).

[7] During the first year of marriage one in every ten couples lives with relatives, according to data for 1960. For nonwhite couples the rate was more than twice that high.

Homeowners were twice as numerous as renters in 1960. Even among young couples married less than five years, every third couple had already started to pay for a home of their own (pp. 394-395)

[8] More women now than a generation ago are sharing in the process of bearing and rearing children. Now only about a tenth bear no children, as compared with a fourth of the older generation. A part of this change resulted from a drop from about one-twelfth to one-twenty-fifth in the proportion who remained single through the childbearing period. At the same time the average number of children has declined from about four to two and one-half (p. 394)

The Effect of Changing Cultural Patterns Upon Women

Natalie Shainess

It is generally agreed that the changes of the last decade have been so great that their extent is hardly recognized. The scientific advances alone are said to equal or exceed those of the last century, which in itself was remarkable. All human beings have experienced massive changes, and any specific changes affecting women have also affected men. Man and woman are interdependent, and each affects the balance and movement of the other.

Before considering the changes that appear to be specific to women, it is necessary to consider the major changes of the decade—the effect of technology and the mass media. In *The New People* Winick has observed changes in personality and social life that reflect a "massive shift of human consciousness." He feels the "new people" have taken over the world, participating in the destruction of old concepts of identity, sexuality, and ways of living. He suggests that the most radical changes of all are in the areas

of sexual identity and sex roles, and that the new tone of life—"a bitter, metallic existence"—may simply not be worth the price of living it. He comments that all extremes are becoming blurred into neuter—a tendency earlier sensed by both Freud and Erich Fromm in their consideration of Ibsen's *Peer Gynt* and the image of the button-molder. Winick also noted the significance of Playboy-fostered voyeurism, nongenital sex, and the general lack of sexual passion.

In Slater's *Pursuit of Loneliness*™ Americans are described as hard, surly, bitter people, fanatically pursuing objects although already surfeited by them, and thus postponing (avoiding?) living. Slater describes the emotional and intellectual poverty of the housewife's role—one that often delivers the *coup de grace* to her early promise.

Arieti has noted a new type of alienation, which he distinguishes from the first type characteristic of the withdrawn schizophrenic individual, or the second, described by Horney, in which the person is cut off from his own feelings, although there is no other gross abnormality. In Arieti's "new alienation" the individual maintains effective contact with the outer environment and seeks ever more stimulation, but has undergone mutilation in his inner life: "Inner conflicts are denied, introspection is frowned upon . . . the person *bathes* in his environment . . . there are no long-range ideals or goals . . . and at times a new kind of depression occurs characterized by

constant demands and claims on others." These claims utilize a projective style, blaming others, and are used by the young in particular to blame "society." Man, Arieti suggests, has become a robot—functioning, one might add, in an overstimulated and undercommitted society.

This conception of current personality and intrapsychic change can be understood, from a genetic vantage point, as relating to another concept of Arieti's, that of volition. He views the inception of volition in the infant toward the end of the first year of life as the capacity for choice in pleasing self or mother—the inception of the capacity to defer instant gratification, leading to that maturational ability to choose the reality principle over the pleasure principle. Thus this viewpoint suggests that permissive childrearing,[1] a change of the last two decades or so, in which mothers—and to some extent, fathers—did not "care enough" to engage in the process of resolving infantile grandiosity, has left this generation grandiose, disconnected, undisciplined, doubtful of self- worth, and empty.

So dehumanization and impulsivity are the all-pervasive undercurrents to any changes being considered. Turning to more specific change affecting women, the contrast with the picture of even a decade ago is very great; of course, this refers to Western woman, and particularly the American woman. Traditional stereotypes of the passive, in some ways delicate, woman, preoccupied with her double role as wife and mother, taking on all of the

gender tasks assigned her—cooking, cleaning, caring for her children, serving her husband in a multitude of ways, and working outside the home, in the majority of cases, only out of economic necessity—all these are passing.

Fostered by social and technological changes, including the perfecting of contraceptive techniques, the general rise in sexual preoccupation, and culminating in the women's liberation movement, a new woman is emerging. She rejects the traditional roles described, demanding individual satisfaction and success. Large families are essentially a thing of the past, and the one-child family, with or without a husband and father, is growing in numbers. The high divorce rate has resulted in women spending longer periods of life alone: most men divorce to remarry; women to get free of an unpleasant situation.

The sexual revolution—meaning, for the most part, free and casual sex —is a very real change, although many still tend to deny this. It is rather unique in terms of its genesis. Fostered in good measure very deliberately by SIECUS,[2] and by the mechanistic and (in my view) methodologically unsound and unproven sex-in-the-laboratory studies and alienated therapy of Masters and Johnson, varied changes have taken place, from lessened guilt and greater freedom for some, to a general tendency to a greater voyeurism and exhibitionism, loss of authenticity, and sexual alienation, on to the setting up of sexual norms that have created new and more damaging demands upon

sexual participation, with "forced change."

While the old double standards have seemingly been abandoned, they are still present in new form, favoring the attractive young woman in her immediate sexual opportunities, but leaving long-range effects still to be appraised, and making marriage a rapidly disappearing option. The distress for some has been great, noticeable at the university as well as beyond, and reported by patients in treatment.

The emphasis on youth and sexual desirability without regard to the *person* has created problems for the older woman. Whether changing values simply mean that women have to pay a price until new patterns are established, or whether it bodes ill for them ultimately, remains to be seen. Lederer, in *The Fear of Women,* makes a significant and disturbing statement that suggests the latter: "Nuclear Age Woman has reason to be concerned about the threats to these (the family, and her value). . . . Men, glorifying in the new technology, visualizing an eventual mastery over nature, accomplished in their own exuberant feats of strength . . . are no longer part of the mother-goddess scheme of things."

These changes have been part of the ongoing blurring of gender distinctions leading to an androgynous society (no value valence is intended here, as there are many facets to change of this kind). The fading of gender

boundaries has been accompanied by fashion change, in the phenomenon of "unisex" clothing and fetishistic styles (the exposed thigh between boot and "hot pants" is a current example) as well as the alienated "hard" and hardware-trimmed space-age type of clothing. Greenson has also observed these changes.

Perhaps toughened by some aspects of the new alienation and student activism, the women's liberation movement has been the greatest single force for change affecting women. It has also been greatly concerned about gender distinctions because these have interfered with woman's status as equals, and studies of gender-role stereotypes have examined the validity of rigid concepts of masculinity and femininity, biologically, psychologically, and socially.

Cultural change has thus affected every aspect of women's lives: the acceptance of gender-role assignments, living style and work, mode of sexual expression, heterosexual relationships including dating style, all aspects of the reproductive function and role including concepts of marriage, family, motherhood and child care, abortion and contraception, and finally gender identity and psychology.

Changing Gender Concepts and Identifications

With regard to changing concepts of gender and gender role today,

including sexual role, Erikson has described the "identity diffusion" of youth today—a lack of firm boundaries, or what might be called a failure of complete severance of the original symbiotic mother- child tie. Erikson notes that the process involved in the formation of identity lies at the core of the individual and also at the core of his communal culture. It involves what Sullivan termed "reflected appraisals" and Erikson calls "simultaneous reflection and observation," the individual judging himself in the perceptions of others and molding himself along those lines. He observed that the media may take a major part in the identity-forming process, usurping the place of parents, and that traditional sources of identity-strength are now only fragments.

Erikson suggests that a new balance of male and female is presaged in the contemporary changes in the relations of the sexes and in the wider awareness spread by the media and technology. He notes the great change between the youth of today and those of 20 years ago. It appears that for many the identity conflict, more hidden than apparent, no longer exists in the same way, but instead it is dramatically displayed in dress. It includes bisexual confusions in sexual identity or a diffusion in which gender distinctions of dress no longer exist: the "hairy, unisex style" is a blatant challenge to parents and authority. Yet there is also a very positive trend among the young to be more collaborative in household tasks, ignoring previously practiced false gender-role distinctions.

With what will the young identify today? This question is most disturbing. Sent early to day-care centers, perhaps never, even in their earliest moments, savoring the sweet experience of an exclusive loving relationship to their mother, they will start their identification process with the dispassionate day-care worker, the mechanical teacher—be it television or machine. Will they identify with the characters created to titillate or to sell learning, like the squawky Big Bird of "Sesame Street," or the colored numbers jumping up and down? Perhaps they will identify with the characteristics of power as revealed in the violence on TV, or the visions of protesters and drug addicts paraded on TV and watched repeatedly as a *pleasurable* immersion in our ills, or the violent TV detective shows in which the female human being is being replaced with an image of the "sex-parts female." Baby dolls have now been replaced with sex dolls, wearing bikinis and sexy clothes. Will their sexual identification be related to all of the pseudo- sex-education films—in or out of school or on TV—in which there is a programmed sexual style and response? Further, these exposures and images appear with ever increasing speed. All suggest the development of a hard, alienated woman who is primarily a sex object, unyielding in interpersonal transactions, and hardly likely to be a nurturant mother. All women will want to work, even as that work loses meaning in itself and is only a means to an end: passing time and obtaining more *things.*

Neutering Process

The neutering process, one manifestation of which has been considered in relation to the new alienation and identity, contains other elements. As a result of technological growth, overpopulation, the increased size of business organizations, the messages spread by the mass media, the concept of team play, the rebellion against authority, and many other processes, a hatred (not too strong a word) has developed for elitism. A competitive resentment at anyone who rises, in nonconforming ways, above the masses, the denial of expertise and its misinterpretation as authority—all of these represent on a more general level what can also be observed on a sexual level: the denial of difference, the comfort and protection in being identical members of society, like sheep in a flock. In some ways it seems a return to primitive tribalism; for example, rock music, with its insistent beat provoking the loosely paired dance of masturbatory exhibitionism, is a reflection of the neutering.

Fostered by Playboy voyeurism (and its hidden premise: "You can be a man without being potent"), the voyeurism of television-filled lives, and by the exhibitionism of the tidal wave of pornography, young men and women seem arrested in the infantile sexuality of the Freudian pregenital phase; that is, sexual expression has increasingly become what was formerly considered foreplay, including acts also considered perversions. These are fast becoming the total aim in sex; they offer the instant satisfaction of partial sex and masturbation to those who want to push a button and obtain a response, like

buying something from a vending machine. The lack of anticipation, yearning, and passion, the too easy availability, the ocean of "sex-object sex" into which the individual is submerged and seems unwilling or unable to escape, especially the use of sexual innuendo in advertising every product from air travel to chutney, the alienation from the person's own sentience—all result in this neutering, eliminating gender difference, disguising anatomical difference, and denying qualitative difference in sexual action and experience.

Social Perceptual Change:
The Demand for Freedom and Equality

Turning to the adult, the rising expectations of women have accelerated in recent years and are both cause and effect of the women's liberation movement. These expectations apply to the social, sexual, and marital spheres, as well as to work and economic considerations. Sociologist Komarovsky observes that women have been hindered by "the old chestnuts" men have offered, and adds that men's "hostility and arrogance have been disguised as benevolent paternalism." She cites Marynia Farnham as an example of a psychiatric "neoantifeminist" (or Aunt Jane) who views feminine assertion as violating woman's deepest needs—the Freudian glorification of passivity and the child-penis equation supposedly characterizing feminine psychology. Komarovsky states that the housewife is discontented today because *"satisfaction*depends upon *aspiration,"* and the aspiration level has

shot up like the mercury in a hot thermometer. "A dozen times a day, events belie the sermons directed to women."

Rossi suggests that equality between the sexes is regarded as an "immodest proposal." She feels that American society has been so inundated by psychoanalytic thinking that dissatisfaction of women with their role is invariably viewed as a personal problem. Ignored by society is the fact that girls often undergo a kind of cultural hazing process, keeping them locked in their assigned gender role at every level of development. Consider the reinforcing effect of a statement by Albert Einstein: "The center of gravity for creative activity is located in different parts of the body in men and women.[3]

Although woman's struggle for greater freedom and equality has continued from earliest recorded history, and was even expressed in Chaucer's *Canterbury Tales* (Tale of the Wife of Bath), Betty Friedan's outcry against the Freudian psychology of women and the bonds of the stereotyped feminine gender role gave new impetus and created an almost tangible new draught in the air. But how have the majority of women responded?

Erikson has observed that the relative emancipation ceded to women by middle-class "self-made men" has been utilized in "gaining access to *limited* career competition, standardized consumership, and strenuous one-family homemaking . . . it has not led to equivalent or actual role in the game of

power." He feels that the fashionable discussion about how women might become "fully human" is really a "cosmic parody," and that it is still amazingly hard for the vast majority of women to say clearly what they feel most deeply. In considering woman's psychic structure Erikson rejects Freud's "wound concept" of female sexual psychology, substituting "inner bodily space"; this is a valid observation, yet insufficient in that it does not include the cultural.

Why the status quo is accepted by many women was strikingly revealed in a statement by a wealthy "professional wife" to a gathering that included a number of professional women. She said: "Taking care of my husband is *my* profession, and it gives me all the satisfaction I want." Its pointedness was made even clearer by the elaborate jewel she was wearing. But why men actively maintain the status quo is even clearer: few people voluntarily surrender power.

As a reflection of women's growing discontent with their position, they are expressing themselves more confidently, and researchers in the social and psychological fields have undertaken numerous studies of gender concepts. Notable among these is one by Rosenkrantz, which concludes that different standards of emotional health are utilized for men and women, paralleling sex-role stereotypes; the very features that are considered healthy in men, such as aggressiveness, are judged unhealthy in women. The reverse also held: passivity, the standard for women, was considered sick for men. Other

studies, such as one by Steinmann, confirmed this.

This observation was also noted by jean Baker Miller, who studied man-woman relationships in terms of the processes between dominant and subordinate groups. She noted the self-criticism of the subordinate group ("identification with the aggressor") and suggested new political directions for women, stating unequivocally that "anger is necessary." Indeed, one aspect of cultural change is the growth of overt anger and the demand for change by women as a group—a group widespread and seeking identity in a determined way, for perhaps the first time in history. The formation of the National Organization for Women was an indication of this change.

A curious side issue is the growing envy by men of certain aspects of the feminine gender-role stereotype, just as women themselves repudiate it. Not the breast-envy or womb-envy of an earlier time, it is now envy of the passive-dependent role and of the presumed idle time spent as the individual wishes, while being supported. Indications of this seem increasingly numerous of late. Women have observed that it is virtually impossible to take a taxi in a large city without listening to a monologue on this theme delivered by the driver, and generally including "how lucky you dolls are."

Sexual Expression and Dating Patterns

Studies have revealed that there is strong agreement in the young of

both sexes on the inherent difference between the sexes in sexual self-concepts and in sexual stereotypes. Yet there is no doubt about the vast change in concepts of sexuality and sexual behavior within the last five years. Effective and easy (though not danger-free) contraceptives, especially the birth-control pill, have contributed, as well as value change. Virginity, perhaps always of ambivalent value, has now come to be considered "something to be gotten rid of"—an alienated, impersonal term in general usage. A female college student echoed the statements of friends, who discussed, not whether they might be overcome (with passion) at the moment and yield to their boyfriends, but when and how they could "lose their virginity." Veryl Rosenbaum, a lay psychoanalyst, has written a sensitive poem describing the current view of the first sexual encounter and the loss of virginity as a "button to be ripped off, to roll in the dust under a shabby bed."

Women seem to feel that frigidity, a symptom of a generation back, has in reality been an accusation against them, and they seem almost frantic in their efforts to overcome this and to live up to the norms set by sex researchers. In the women's liberation movement the concept of anything beyond clitoral orgasm is denied, with Anne Koedt's "The Myth of Vaginal Orgasm" as a banner. Many psychiatrists have adopted this position as well. But while basically rejecting Freud's feminine psychology, I still see Freud as correct in postulating a vaginal response. I view the clitoral as a partial response, lending itself to "instant sex-on-demand" from manual stimulation.

Concern with orgasm has become enormous and omnipresent, leading to what has been described as "orgasm worship." Noted along with this is the erotization of language and the use of sexual imagery to describe other problems.

Frequently dating patterns among young college students seem to be exercises in instant sex and nonrelationship, leading nowhere. A college senior had a blind date arranged with the brother of a girl she knew. He arrived at her apartment and within ten minutes announced that he was "horny." She thereupon felt it was incumbent upon her to relieve that state. She appeared as devoid of feeling as Camus' *Stranger*, who seemed to move through life without feeling, even without motivation, going like a vehicle along some predestined track, at a preordained pace, taking turns that he had no part in choosing. The Stranger attends his mother's funeral, even though he has no feeling for her, not even hate, meets a girl, goes to the beach, commits a senseless murder—and the reader is left wondering why, why? He is a new human among us, Camus' prophecy of the new alienation—a man of the Homey type of alienation on the verge of Arieti's third type: beginning to seek sensory experiences to submerge in. It is not by accident that the beach, a place for fun, is the setting for murder. But returning to the girl described, she *did* note the young man's failure to call her again—the failure of her perhaps manipulative use of "instant sex" to buy a relationship.[4]

As another example, a young professional woman, despairing of marriage prospects, decided to give up all restraints on sex. A friend arranged a holiday weekend date for her with a highly eligible young man. There was noticeable evidence of her self-esteem plummeting as she followed blindly her predetermined course. He departed the city without saying good-bye, but had time to comment to the mutual friend: "Say, that was a superchick you fixed me up with!" The young woman's subsequent depression almost resulted in a literal enactment of her symbolically suicidal behavior.

The problem generally seems to be that rejection of the "good" or "bad" value in relation to sexual behavior has left young people bereft of any other standards. Most lack the ability to evaluate sensibly the so-called situational ethics. Here is need for sex education, in terms of value in the individual's development and in interpersonal relations.

Halleck has noted that in spite of the sexual revolution, matters have not changed considerably for young women. The double standard, perhaps in a new form, persists because there cannot be equality in sex without total equality, especially in the distribution of power. "Women lose power and status when they become too indiscriminate in granting their sexual charms, or when their sexual attractiveness begins to wane."

Gloria Steinem has commented on the fact that "men wise in the ways of

power understand its sexual uses well." Perhaps the ugliness of sex in return for status and power on both sides of the equation is more clearly revealed in the involvement of glamorous young women of the entertainment world with top political figures—a long-enduring but recently accentuated pattern. Sex, of course, has always been a woman's ticket of admission to the social scene, but it has now become virtually the *only* means, as little else enters into relationships. It incurs dangerous new risks for women.

The "singles bar" is a relatively new development in the United States, appearing especially in large cities. A manifestation of the growing hold of drinking alcoholic beverages on social style, these bars are establishments where men and women go with the acknowledged purpose of meeting for quick sexual liaisons. A very personable young male patient reported on his escapades via this medium. Although he appeared the soul of innocence and safety, he was something less than that, and it became unavoidable to reflect upon the risks young women were taking, in leaving a bar and going off to the apartment of a total stranger after a couple of drinks, and without telling anyone of their destination, as is common practice. Although no murders, to my knowledge, have as yet been reported, it seems inevitable that they will appear. This approach to sex exemplifies the new alienation, in terms of instant precipitation into sensual experience devoid of inner meaning—the "drug kick" of the deadening of cognition through alcohol, and the instant immersion into sex with anyone. The new language of sexual request or

invitation reflects the new alienated style. As reported in *The New York Times,* a man asked a woman he had just met: "Would you like a sensual visitor tonight?"[5]

Sexual liaisons of young women, whether with young or older men, seem to conform to a style of abandoning their own pursuits in good measure and going to live with the man; however, there seems to be a local style involved, and in some cities the reverse is true in location, but not in who makes the major life change. This self-abandonment, in the face of the current struggle for equality, seems another aspect of the new alienation. Seidenberg has pointed out the problems of sexual inequality, especially for the gifted young woman of today who wants to share intellect as well as sex.

A new sexual aggressiveness in women has also manifested itself, visible in virtually assaultive passes at boyfriends in the street, who seem to endure rather than enjoy it. These have been in line with images fostered by the mass media as well as by sex researchers. In contrast—and perhaps astonishing to the older generation—is the practice of "bedding down," of college-age boys and girls sleeping together without anything sexual transpiring. It seems a mode of obtaining comfort, to alleviate what could be called a "babes-in-the-woods syndrome," and also a manifestation of the neutering process going on.

With greater experience women are sexually wiser, have expectations of men as lovers, and experience a growing discontent. Many men are finding these expectations hard to live up to, especially since they cannot as successfully disguise or deny their inadequacies. Perhaps the new insistence on the normality and desirability of sex play that was formerly considered perverse is an effort to compensate; again it suggests a sexual neutering process. To the author it appears that *passion* favors genital sex.

Along different lines an old, and yet new, sexual style has developed— new in the sense that the age disparity of incest-model dating has grown in sexual relationships of very young women with considerably older men. From reports—and to be observed on the streets—young women in their late teens are to be seen with men easily in their fifties or even sixties. The "anything goes" concept of sex, together with the new alienation, seems responsible for this, and young women do not seem aware that they may be "selling themselves short." Judith Viorst wrote a delightful poem called "A Lot To Give Each Other," capturing the lack of commonality in anything but sex: "He worries about his prostate, and She worries about her acne, and He was born before television, and She was born after running boards—but they feel they've got a lot to give each other . . ." The reverse young-old pattern with women as the older partners, of which there are always a few instances among the wealthy, seems not to have caught hold. In the light of the aforementioned change, many men are living in a "captain's paradise," that is,

they have a girlfriend (young) and a wife over a period of many years. But, of course, it is not always pure fun for such men, some of whom are compulsively trapped in a dual relationship, which serves deep neurotic needs and is at times quite punishing.

The Older Woman

For the older woman new problems seem to exist, and the new sexual freedom is proving to be a bad check. If married, and unless there has been an extraordinarily satisfying marriage, there is a drifting apart of all interests including the sexual, especially as the large corporation has made increasing demands on men and offered all kinds of "rewards." Infidelity has become almost a norm. Jessie Bernard has indicated that sex researchers have *promoted* the acceptance of infidelity. An example of sexual image-making is to be seen in Neubeck's book,*Extramarital Relations,* in which virtually the first words to meet the eye, in big bold type, are: "WE ARE HUMAN." It is an instance of incitement related to the indulge-yourself philosophy of the times, also expressed in a common phrase of late, especially by men: "After all, we're not going to pass this way again." Unverbalized is the concluding phrase: "so grab everything you can."

Although Bernard questions the hurt involved if infidelity is not known to the partner (and the impression is that it is *always* known at some level),

she does note that it is much more commonly acted upon by men. Wolf notes that in a patriarchal society there is less infidelity by women. He also observes the stress added to the wife's role by the image she must fill as an organization wife. Yet he feels there is less hypocrisy in marriage today. Quite aside from the fact that marriages that do not have common goals are in the process of destruction, Bernard fails to note the social and economic base to infidelity—in short, the power distribution makes infidelity by men more possible, while women have a history of accepting hurt, or settling for the most likely means of survival. My impression is that infidelity, whatever its basis, always causes a serious wound in either sex, however it is glossed over. When the interests of two partners diverge, marriage becomes a precarious living arrangement.

The problems of aging for men, aside from the inherent psychological components of the experience, relate primarily to retirement at an age when still valuable powers and capacities exist, so that Goodman Ace has humorously suggested a "Used Man Lot" to deal with the problem of male obsolescence. However, the older woman's problems are even more serious. She has to contend with the menopause, which seems to punctuate the approaching end of her sexuality and her life, at the same time that she must cope with the "empty nest syndrome"—the end of her major life role as a mother. Where her stereotyped gender role, into which she has been molded, has not been tempered by any other interest or any activity bolstering self-

esteem, her emptiness is experienced by her as a defect, and she is likely to "crack." She views with horror the long period of life—empty life—still ahead of her in the face of her tenuous relationship with her husband, whose interest is virtually nonexistent or turned elsewhere. One divorced woman in her forties reported a dream with a single visual image: an empty suitcase. In associating to the dream, she recalled the suitcase as an expensive one belonging to her former husband, usually stored in the closet, and now scratched and worn. She said: "I am alone and empty. I am unused as a woman. I am no longer valued, even by myself."

Fortunately women have begun to solve the problem belatedly by returning to study and work—although often at a level far below their neglected abilities. Yet this situation, compounded of "social maltraining" as well as personal difficulties, often results in serious depressions, as Rose Spiegel and others have stated.

For the older woman alone, social isolation is a singularly punishing reality in a paired society, especially for the woman who sees herself as only capable of the passive feminine role for which society ordains her. The combined despair and anger this elicits was revealed in a Christmas card sent me by an attractive but faded widow in her early sixties, who had arranged a consultation because of depression. When it seemed little could be done for her, the unreality of her approach to life in "waiting for my Prince Charming

to come" was pointed out, and it was suggested (without complete conviction, it must be acknowledged, since nothing compensates for the lack of a close relationship) that feelings of pleasure and reward would grow as she undertook some useful activity, the various possibilities of which were explored, although rejected by her. The card contained the following note: "Although I feel so disheartened because my contacting you was such a dismal failure, I am truly appreciative of your having seen me."

This predicament of the older woman alone has been well documented by Isabella Taves, who observed her sexual as well as social dilemma: she must either engage in transient or (rarely) enduring sexual encounters with married men or live a celibate life. The divorced older men who remarry almost invariably seem to choose a considerably younger woman. As a professional man put it to a female colleague when discussing his own remarriage: "Why should I have undertaken the problems of marrying an older woman, when I can have an attractive, sexually appealing young woman who will wait on me hand and foot, be happy about what I can give her, and make few demands upon me? And it makes me feel young to start a family again." As logic it seems unassailable, but it spells a serious existential dilemma for the older woman, especially as her value as the *person she has become* seems nonexistent, and her sexual life must either become degrading or disappear. One 39-year-old attractive divorcee, who had several affairs with inadequate men out of desperation, asked: "Why aren't there men to

appreciate the sterling qualities my friends insist I have?"

Marriage

In general, brittleness and unyielding self-centeredness of an almost militant nature seem to characterize marital attitudes of both sexes today. Perhaps the fact that for women, marriage with conventional gender-role stereotypes has often been a trap, a situation symbolized in Sartre's play *No Exit,* has contributed to this. Marmor points out how psychoanalytic interpretations of a woman's rebellion in a marriage depends upon the analyst's point of view, and whether he espouses the view that passivity is normal for women. Seidenberg also calls attention to the unfair expectations of woman's role in marriage, both in life and as portrayed in literature. And philosopher John Stuart Mill has givenus one of the most moving and clear statements about what is wrong with unequal marriage, and what marriage can achieve with true equality and communion between partners. His view, of course, particularly relates to intellectuals.

Symonds has characterized the developmental restrictions of marriage for many women, and the symptomatic expression of the problem, as "Phobias after marriage: woman's declaration of dependence." She points out that phobias are the women's way of handling repressed anger within the marriage, and that with growth the marriage is often disrupted, as the

fundamental nonverbalized premises are challenged. Yet up to now working and professional women have not greatly challenged these premises and still undertake the Herculean effort of doing what amounts to three or four jobs at once. Caroline Bird, whose social study of the inequitable position of women broke ground for the women's liberation movement, recently pointed out the added advantage that men, and professional men in particular, have in wives who serve them personally and help them professionally. As professional women ruefully remark: what every successful woman needs is a *wife*!

Although the majority of women still seem satisfied with, or accept, the stereotyped view of marriage, as Komarovsky has indicated, or even have a false view of marriage as freedom in the sense of escape from the childhood home, there is a gap between expectations and reality. Among blue-collar workers Komarovsky found that the male was dominant in the marriage and that the threat of violence was an important basis for this power. She also pointed out a very important consideration in marriage: the individual partner's bargaining position depends on the degree of emotional involvement, which is one factor explaining feminine subservience. Yet caught in the crosscurrents of social change, women feel growing disappointment as some of the compensations of an earlier time have disappeared, and they find marriage less rewarding. As one woman, a professor of psychology, expressed it: "Marriage has become a living arrangement." Certainly less is heard of intimate relationship or of love, and

more is heard of life style and sex.

Marriage as an institution is seriously embattled, and all sorts of alternatives are proposed, as Otto suggested, including serial monogamy, marriage networks, and open marriage, among others. Greene believes that the individual may be carrying out a neurotic repetition in sequential marriage. Yet the new choice may also be a good one, and the result of growth. Unfortunately women seem to have less opportunity for positive change by the time growth has occurred. Extreme woman liberationists support these alternative concepts, or deny that marriage can be viable in any form. From a psychoanalytic viewpoint, although undoubtedly some early choices of marital partner are predominantly neurotic mistakes, transference distortions and narcissism (self-centeredness) are still the major factors in marital failure, but the distribution of power in marriage is increasingly recognized as a determinant of workability.

Many express a belief that marriage and the nuclear family are failures, and some of the young have entered communal living arrangements and communal marriages. A famous illustration was that reported as a "course in communal living"—an experimental college set up at Columbia University.[6] Yet no change is ever monolithic, and many young college students are marrying legally after living together in experimental marriages. These are healthy marriages based on a satisfying relationship, not entered into out of

fantasied expectations and sexual guilt. Many young couples write their own marriage ceremony, stressing equality and mutuality. Along with these changes sometimes goes the perhaps synthetic type of back-to-nature ceremony, complete with barefoot bride in see-through dress without underclothes. Of course, some of these experimental marriages are legalized because of the young woman's pressure: the nest-building tendency is still a part of feminine nature— and a valid one. On a positive note Rostow suggests that the newer concepts of marriage hold it to be a process in which the husband and wife cooperate on many levels to permit each separately and together to satisfy needs and achieve goals.

As part of the rejection of marriage, and while undoubtedly determined by other and unconscious forces, there has been a rise in lesbianism. Radical women seem to make a conscious effort in this direction, as part of an attempt to eliminate men from their lives. As one college girl, who was "trying out" lesbianism, put it, "If only my friend Vera had the head of Jane Fonda, and the body of a man!" Retreats and encounter weekends fostering lesbianism have become almost commonplace. This undoubtedly relates also to the growing reluctance to undertake motherhood.

Abortion, Mothering, and Child Care

In this aspect of women's lives some strange paradoxes are to be found.

On the one hand, in spite of the range and availability of contraceptives, the one-parent family, consisting of unwed mother and child, is notably on the increase. There seems to be a kind of defiant pleasure in the pregnancy—in the street many girls seem to take pains to be noticed as pregnant. One gets the impression that this is their weapon against mother and society. But there is a large faction who totally reject the idea of motherhood, which Betty Rollin described in a *Look Magazine* article as "as unnecessary as spaghetti." Yet many, married or otherwise, insist upon having children despite their reluctance to care for them, and they call for crèches for infants and child-care centers as a regular aspect of child life from birth on. That is, they seem to choose biological, but not nurturing, motherhood.

On the other hand, women are demanding the right to total control over their reproductive function, including abortion. Their efforts, coupled with those of physicians, psychiatrists, and attorneys, have brought about great change—a subject too wide to document here. However, psychiatrists have been slow to realize the unfairness and unfortunate consequences of unwilling motherhood, or to come to a conclusion that it has taken me a long time to clarify and state simply: there is absolutely no relationship between theological dogma and mythology and intrapsychic experience for women, who *must* resent an unwanted pregnancy, and who carry their resentment over *unalterably,* whether consciously or not, into their affective relationship and dynamisms with the child. In the past women have been expected to be

Christlike, carrying their crucifix within; they have often been sanctimoniously counseled by some who have had rather casual attitudes toward the act that placed women in this position and little empathy for their circumstances. The plethora of research now going on to ascertain the effects of abortion or its refusal is belated and almost ludicrous, in the light of the years of cruel entrapment of women by refusal to recognize their needs and best interests—without benefit of research!

Women are beginning to see the relationship between social mythology and reality; and those freed from the "psychological set" of having to defer to men are very clear about it and are taking effective action. They have begun to realize that the refusal of abortion can also be seen as a power mode to restrict sexual expression, but only by *one* sex, or, politically, to enlarge a specific group. In any event the tide is turning.

How will women ever solve the career versus motherhood problem? This is a difficult dilemma. Women have an added burden if they wish to function as both human beings and females, and it is hard to avoid the feeling that they must give something extra to achieve their goals. It does not seem in the best interests of children and society for women to attempt to live in exactly the same style as men. Women's lives are perhaps more phase-oriented. It seems as if women should receive support from society to spend a few years with their young children, with the assurance that a place will be

made for them when they return to their outside endeavors. Perhaps they need to be subsidized during the early mothering period, until child-care centers can take over. They also need more help from men, who have largely been absentee fathers, and who will gain from their wives' efforts. Already there is evidence among young couples of a change in the direction of a more participant father role.

My own solution, which I was fortunate in being able to carry out, was to stop my professional involvements—in all but a few limited instances—until my children were attending school full-time. The opportunities for any informal kind of study under such circumstances are great. Inevitably, of course, it does entail sacrifices and losses, certainly compensated in large measure by the evidence of happiness and growth in the child, as well as by the close relationship itself. Undue attention to the ease with which men direct their lives can be embittering. But as a corollary, men need to be more generous and more helpful in aiding women to do their best. For women whose work is an economic necessity when the children are small, or who flatly reject child care, obviously child-care centers are the answer.

Conclusion

Whether compounded of pessimism or a realistic appraisal, the impression persists that the direction in which the culture is moving is

toward the creation of male and female "humanoids," becoming still more alienated, mechanical, unfeeling, compulsively cruel, asexual but sexually preoccupied, frantically trying successive modes of sensual experience including drugs, devoid of the capacity for deep relationships, and with an increasing will to power by any means. The society of the on- rushing future, which is already today, has not only veered from the repressive to the expressive—it has lost its humanity along with its superego.

More specifically, the cultural factors affecting women are multidimensional, and in some areas they are in direct conflict. Women are more direct—and "harder." They demand social equality in every form, yet a majority are slow to seek or accept change, which has always been promoted by the young. They are sexually freer, yet also sexually compulsive and alienated. They have not gained too much through the "sexual revolution." They, as well as men, are less totally involved in the marital relationship. As a group they have considerably less interest in motherhood. And many are tending to doubt psychiatry's ability to help them.

Implications for Treatment

How will psychiatry function as the changes relating to alienation grow? The zenith of human understanding, peaking with the appearance of Freud, Adler, Sullivan—to select a limited few as representatives of aspects of

thought about inner experience and relationships—seems already to have begun to decline. The behavioral therapists, the symptom modifiers, and the "containers" will deal with the *symptoms* of an expanding human illness: alienation and the loss of humanity, in some ways an even greater problem for women than for men. Perhaps social psychiatrists and psychologists will join them to deal with broader aspects of this illness, but there is little ground for optimism about constructive change.

On the other hand, the degree of change and its effect upon women within the last decade suggests something not sufficiently recognized: human beings are remarkably plastic, and great care should be taken before considering psychic and behavioral expressions innate. Perhaps the most significant fact of our time in relation to treatment generally, and with regard to women specifically, is the necessity to understand the social setting of problems as well as their interpersonal determinants, rather than regarding them as exclusively intrapsychic in genesis.

Social psychiatry applies to the individual as well as the group, and a new concept of preventive psychiatry and treatment has been described by Robert J. Lifton as "Advocacy Psychiatry." Here he extends the view of Sullivan that the therapist must be clear about his own values yet not impose them on the patient, to examining the integrity of values and attempting social change where indicated.

In this sense Freudian feminine psychology, which has been nibbled at by dissenters, but not challenged as a totality, *must* be supplanted. Ideas of feminine passivity as health and the necessity of deference to masculine interests must be jettisoned if women are really to be helped to mature and attain reasonably satisfactory lives. Mastery over their own bodies and reproductive lines is essential for women's emotional health and emancipation. The recognition that *all* humans are aggressive at times, that it is not a particularly desirable quality, but no worse in women than men, although more in conflict with male societal expectations, is another essential basis to good therapy for women. And again, as with all human beings, women must be helped to become as free of anxiety as possible and to learn collaborative modes of relationship as equals.

It has been suggested that there is psychologically *no* difference between men and women, except perhaps as a remote component of their biological sexual representation, in terms of receptiveness in a woman, the quality of being penetrating in a man. But even these are distorted by other processes. For women any specific feminine psychology relates only to the significant nodal points of their developing reproductive function. These have yet to be properly organized into a body of psychological concepts, although the direction is suggested.

May Romm has asserted that "the thinking woman can no longer accept

the demeaned and submissive role implied in the statement 'Anatomy is Destiny.' " She feels women must be brought into the category of homo sapiens. So what emerges with great clarity is that male therapists, and female, too, who have previously been either unquestioning of or insistent upon old theories, must scrupulously examine their own gender concepts and prejudices, *listen* carefully to women patients, and search for the *setting* of their discontent, depression, or sexual unresponsiveness—and, indeed, other kinds of symptomatology that have been used perhaps more accusatively than therapeutically. Here the choice of language is an important modality to note.

Lastly awareness of the three modes of alienation suggests a way of leading women back into contact with themselves—an important issue for men as well. Certainly it has been my experience that many a rebellious, angry, or destructive young woman has been led along the path of introspection to greater rationality and more rewarding or vital living, after she has had a chance to perceive that stereotyped, and sometimes demeaning, labels have not been pressed upon her.

Chapter 23

The Psychobiology Of Parenthood

Therese Benedek

Introduction

The pleasures and pains, the gratifications and frustrations of parenthood are existential components in the adult life of humans. In spite of the ubiquity of its problems, the psychology of parenthood has not been studied systematically. Science progresses slowly. Generations of scientists labor arduously to build the foundation for an insight that a genius formulated long years before. I refer here to a statement of Darwin: "The feeling of pleasure from society is probably an extension of the parental or filial affections, since the social instinct seems to be developed by the young remaining for a long time with their parents" (p. 6). It is obvious that Darwin, the naturalist, arrived at this insight from innumerable, seemingly unrelated observations. Today the verity of this generalization appears evident to students of behavior, whether the objects of observation are human, subhuman mammalians, or the lower levels of the evolutionary scale.

Psychoanalytic theory is (primarily) a biological approach to psychology. Psychoanalytic investigations of various aspects of behavior afforded the framework within which biology, psychology, and sociology as continuum can be explained. This brief essay written in such a broad setting can serve only as an outline. At the same time it intends to show that parenthood is the focus in which biological, psychological, and cultural factors converge.

More than ever before, parenthood in our age, as it evolves in individuals reared in our culture under the pressure of a rapidly changing civilization, appears removed from its biological sources. Parental behavior, as a culturally molded pattern, and its individual variations, are focal points of psychological and psychiatric studies of children and adults, but the psychodynamic processes of normal parenthood have not been conceptualized, as if taken for granted. Since it was assumed that personality integration is achieved during adolescence, the genetic theory of psychoanalysis does not include the psychodynamic processes of reproduction and parenthood as drive motivations for further development. Yet investigation of the psychosexual functions of women has demonstrated that personality development continues beyond adolescence under the influence of reproductive physiology, and that "parenthood utilizes the same primary processes which operate from infancy in mental growth and development" (Benedek, 1959 p. 389)

Theoretical Considerations

The instinct of survival in the offspring assures the survival of the species. This instinct is considered the organizer of those complex species-specific behavioral patterns through which survival of the species is maintained. The drive organization has three consecutive phases: (1) the sexual drive, which motivates courtship and mating behavior; (2) reproductive physiology, which accounts for the maturation of the germ cells (gametes), sets in motion the processes that maintain the fertilized ovum, supports its maturation, and guides parturition; (3) the care of the offspring, which, although it takes place outside of the mother's body, is a part of the reproductive physiology. Strictly under hormonal control in all species, the care of the offspring in some nonmammalian species is the function of the mate. Mothering behavior of human parents can be modified and divided between the sexes, either by choice or by necessity.

The phasic evolution of female sexuality exposes to investigation the drive organization of the propagative function. In Chapter 28 each phase of the female propagative function is discussed. Here will be pointed out only those aspects of the female drive organization that elucidate the difference between the sexes.

Investigation of the woman's sexual cycle revealed the development of the sexual drive. The psychodynamic tendencies that characterize the phases

of pregenital development are repeated in correlation with the evolution of the gonadal cycle. The pregenital tendencies (oral, anal, and pregenital) are integrated in the mature sexual drive, which reaches its peak at the time of ovulation and regresses again during the premenstrual-menstrual phase. The pregenital tendencies are manifestations of the *primary instincts* that maintain the homeostasis of the organism and secure its growth and maturation so that the *secondary, sexual instinct* can come to the fore at puberty. The slow, phasic evolution of ovogenesis in woman exposes the integration of the sexual drive through the psychological manifestations that accompany the hormonal cycle. Although such investigation probably cannot be performed in men, one may assume that man's sexual drive is derived from the pregenital tendencies during development from infancy to puberty.

Characteristic of man's sexual drive is its plasticity. "Sexual energy," its "appetitive strength," and the "intensity of its consummatory behavior" (for the sake of brevity, ethologists' terms are useful) are constitutionally "given" individual characteristics molded by ontogenic development. The regulation of sexual need and activity is central; hormones induce changes in the nervous system by affecting those systems that coordinate arousal and mating behavior. While courtship and mating represent the most accurate coordination of hormones and behavior for all the vertebrate species, this is not wholly true of infrahuman primates. In regard to man, history, as well as current anthropological and cultural changes, masks the hormonal effects

from the physiology of the procreative function.

Women became independent from the limitations of estrus. The factors that promoted this evolutionary fact continued to interact with intraorganismic and environmental conditions and increased the gap between sexuality and procreation. The characteristics of the sexual drive hold true for both sexes. They motivate and integrate the sexual act, which may or may not be in the service of procreation. In women the integration of the psychodynamic tendencies that accompany ovulation indicate that motherhood has an instinctual origin; thus one may speak of "mother instinct" in scientific terms.

But what about man? Man's role is discharged in one act that does not involve tissue changes beyond the production and deposition of semen. This process is under hormonal control. The innate specificity of the procreative function expresses the fundamental difference between the sexes. The psychophysiological organization of the male serves one act, that of insemination; the psychophysiological organization of the female serves the function of pregnancy and motherhood beyond the mating behavior.

This raises the question, what about fatherhood? Are men trapped into the social (sociological) role of fatherhood just by the compelling desire for orgasmic discharge, or does there exist in man a primary instinctual tendency

toward being a father, a provider? The biological root of fatherhood is the instinctual drive for survival. The drive organization of species survival has three phases differently employed in the sexes. In phase one both are equal; in phase two the function of the male lasts a short time; in phase three the male of all species is involved for the time necessary for the maturation of the offspring. In Homo sapiens man's biological function as provider reaches beyond the maturation of the children; it reaches even beyond the family; it is a source of socioeconomic organizations. Since the biological role of fatherhood is to protect and thereby to provide the territory that secures the survival of the pair bond and their offspring, is there a psychobiological source of the quality that we term fatherliness?

Fatherhood, fatherliness, and providing are parallel to motherhood, motherliness, and nurturing. Fatherhood and motherhood are complementary processes that evolve within the culturally established family structure to safeguard the physical and emotional development of the child. The role of the father and his relationship to his children are further removed from the instinctual roots that make his relationship with his children a mutual developmental experience. Fatherliness, like motherliness, has two sources; one is the biological anlage; the other is rooted in developmental experience. Yet there are differences between the sexes regarding the evolution of these primary attributes of parental behavior. In the development of fatherliness, the biological bisexuality and the male infant's

biological dependence on the mother are primary factors.

Bisexuality is a biological attribute of both sexes. The propagative functions of nonmammalian vertebrates offer striking examples of the different distribution of courtship, preparatory activities, and especially care of the young. In many instances the male takes over the care of the deposited ova or the feeding of the young as the instinctual organization of the species requires. Even in mammals there are examples of the male's participation in the care of the offspring. Nature seems to be able to reach deep into the bisexual propensities to meet the need of adaptive processes in a species. Our knowledge of man's bisexuality is still very limited. Investigation has been impeded by cultural denial. Hormone chemistry has helped but little since androgenic and estrogenic hormones, even progesterone, are closely related compounds; they occur in both sexes; their function in relation to symptoms has not been clarified. In the last decade intensive research has been conducted in relevant fields in an effort to clarify the role of "normal bisexuality" in man. Some level of predisposition may be seen in the varying degrees of aptitude men show in the performance of mothering functions with their own babies. One also observes a great variety in women's skill and aptitude for genuine motherliness. The inhibition of these primarily biological functions may be attributed to the bisexual anlage of woman. The behavioral manifestations of the biological anlage, however, are strongly influenced in both sexes by the developmental process, especially that of the oral-

dependent phase.

Every man's earliest security, as well as his orientation to his world, has been learned through identifications with his mother during infancy. In the normal course of male development this early identification with and dependence upon the mother are surpassed by the developmental identification with the father directed by the innate maleness of the boy. This results not only in the sexual, oedipal competition with the father but also in multiple identifications with the various roles of the father as protector and provider. In the development of the girl the infantile identifications with the mother reinforce the gender anlage and facilitate the normal evolution of female sexuality.[1]

The primary drive organization of the oral phase, the prerequisite and consequence of the metabolic needs that sustain growth and maturation and lead to differentiation of the procreative function, is the origin of parental tendencies, of motherliness and fatherliness.

Parenthood

The term "parenthood" refers to a psychobiological status of great significance for the individual and for the society in which he lives. Becoming a parent means being a link in the chain of generations. "It is only Homo sapiens who has the distinction and the responsibility for raising children

beyond that procreative cycle which produced the particular child to full maturity and adulthood" (Benedek, 1970 p. 119) and so to convey to their children not only what the parents inherited (with the genic code) but also the complex culture with its ethical restrictions and potential gratifications.

In this chapter parenthood is presented from two viewpoints. First, the parents' interactions will be characterized in relation to the phasic development of the child; second, parenthood will be viewed as a crucial experience during the life cycle.

Marriage and family structures evolved as the consequence of the lengthy dependence of the human child. The family is the psychological field in which the transactional processes between parents and between parents and their children take place. The core of this field is the husband and wife, who bring to their marriage particular personalities as they have developed from infancy in transaction with their own parents, siblings, and other significant persons and events in their environment. Manifold and often tenuous reciprocal adaptations occur in every marriage until the couple is welded biologically through parenthood. Heterosexual love alone is not a guarantee of a lasting relationship. The ability to maintain a lasting relationship, which secures the permanence of a marriage, depends on the total personality of each partner. It requires of each a self-organization that does not become discouraged by the changing aspects of love as an

experience, since it invests the marriage as an institution with (narcissistic) libido. If such self-investment exists, the feedback of being married and being a parent supports the interpersonal relationship between the marital partners through the vicissitudes of marriage. Speaking not of happy but of enduring marriages, it should be emphasized that, stimulated by the ongoing psychodynamic interaction, the personality of each partner achieves another level of integration. The process of mutual maturation gains another dimension through parenthood, through relationship with the child, through communication with each other via the child.

The carrier of nonverbal communication is empathy. Empathy can be defined in psychoanalytic terms as a psychic energy charge that directs attention, facilitates perception, and furthers integration within the psychic apparatus. In general, empathy enlarges the psychic field of any individual and enables him to encompass in his responsiveness everyone and everything to which he may relate. While empathy itself is unconscious, the empathic response usually appears as an intuitive, spontaneous reaction that often mobilizes affects and motivates responses. In our culture many individuals are so guarded against their intuitive feelings that they suppress their primary empathic responses even in the most intimate situations, such as sexual interaction, and even in their transactions with their children.

Closest to its biological source is the mother's empathy for her infant.

This determines the quality of her motherliness and leads to competent, successful mothering. The adjective "competent" calls attention to another level in the use of empathy. As the child develops and becomes more and more a person in his own right, parental empathy has to undergo intrapsychic elaboration. Empathic response is a direct instinctual or intuitive reaction to the child's need. Empathic understanding is arrived at by a preconscious process of self-reflection that leads the parent to an understanding of the motivations of the child's behavior and at the same time to an understanding of the motivations of his own reaction.

What is said about the empathy of the mother also holds true for the father. Although the father's empathic response to his infant cannot be related directly to his function in procreation, most men do exhibit genuine fatherliness. Fatherliness, like motherliness, is an instinctually rooted character trend that enables the father to act toward his child or toward all children with immediate empathic responsiveness. Fatherliness has early and differing manifestations. It seems to appear in the father's first smile greeting the newborn; it is expressed in his ability to cradle the infant securely; or later it is displayed in his participation in the care of the infant, in his patience and tolerance of the disturbance and difficulties that naturally arise in rearing a child.

The psychobiology of fatherhood seems to have evaded investigation as

if it were hidden by the physiology of male sexuality and by the socioeconomic function of fathers as providers. While biology makes invariable the role played by the mother in the propagation of the species, the role of the father changes with cultural and socioeconomic conditions. Surprising as it may appear, the socioeconomic function of providing as well as the characterological quality of fatherliness are derivatives of the instinct for survival.

Only human parents have two sources of parental behavior. One is rooted in physiology as in any other creature; the other evolves as an expression of the personality that has developed under environmental influences that can modify motherliness and fatherliness. After the child outgrows his infancy, the mother becomes more independent of procreative physiology. Thus the motivational system of parental behavior becomes the same in both parents. Parental behavior is motivated by the response to the actual need of the child, by the situation in which the need arises. The unconscious motivations of parental behavior are rooted in the personality. This colors the meaning of the parental experience and stimulates anticipations that parents project onto their children often before and more concretely after they are born. Indeed, Freud was right when he stated that the tender love of fond parents for their children originates in the narcissism of the parents, in the libido reservoir that maintains motherliness as well as fatherliness.

It is not possible to outline the normal range of motherliness and fatherliness in action. The limits change from culture to culture, from individual to individual. When we consider motherliness and fatherliness as developmental attainments in close contact with instinctual sources, we become aware of their oscillations. For motherliness and fatherliness appear to fluctuate under affect; they seem to regress and reintegrate in interaction with the child and his total environment.

Infants learn to anticipate the parents' responses faster than adults imagine. The significance of the child's anticipation of the parent's reaction to his behavior has been studied in detail from birth through adolescence. The balance between the child's confident expectation of gratification and his fear of frustration modifies his sense of security with his parents. The reciprocal process in the parent rarely has been studied. It is, or used to be, generally assumed that the adult parent's ego organization is not subject to change under the influence of his object relationship with his infant, with his growing child, and even with his grown-up child. Probably such self-secure, mostly authoritarian parents still exist in other civilizations. In our culture modern parents cannot even envy the security of the Victorian parent. Soon that generation will be parents whose grandparents were raised by Victorian parents.

The parent's emotional security toward the child, even when expressed

as authority, has a double function. It protects the child and insures the parent against being unduly affected by the child's behavior. His authority helps him to repress or deny his fears and negative anticipations about the child and about his own ability to cope and love at the same time. The anticipation of negativistic attitudes in their children makes parents insecure, afraid, and often angry even before the child gives them cause. This mobilizes primitive behavior that, even though it may be appropriate, is followed by a sense of guilt in modern parents. The guilty feelings may increase the insecurity, and so a negative spiral evolves between parents and child.

Fearful insecurity is characteristic of young mothers, especially with their first child or with a child who is not healthy or normal. In patriarchal families fathers usually felt uninvolved with and not responsible for the care of the infant. In the young families of our age fathers feel involved and consider it a duty to help their wives. Not infrequently they prove themselves more secure in handling the newborn than the young mother. This, however, may have a negative effect on the wife, who, feeling inferior in performing this innate duty, may become depressed and alienated from the child. Such an incidence illustrates that the emotional balance of the family triangle depends on each of the participants, that to provide a satisfactory environment for the growth of the child, the parents' empathic understanding for each other is a prerequisite. Conflicts arising in the primary triangle—father-mother- child— that originate within the parents certainly influence, at least transiently, their

behavior toward the child, but this seems secondary in regard to parenthood as a developmental process. This concept refers to those transactional processes between parent and child that, motivated by the phasic libidinal development of the child, reactivate in the parent old conflicts of the same period.

The transactional processes of early infancy can be easily conceptualized since in the mother and child they originate in primary biological needs; in the father they probably originate in the formidable adaptational task of becoming and being a father.

Based upon the model of reciprocal interaction between parent and child during the oral phase of development, we may generalize that the spiral of transactions in each phase of development can be interpreted on two levels of motivation in terms of each participant. The parent's behavior is determined unconsciously by his developmental past and consciously by his immediate reaction to the needs and behavior of the child. By incorporating the many traces of the parent's behavior, the infant learns and so acquires a past that enables him to anticipate the parent's response to his behavior. This introduces a third aspect into the motivational pattern, namely, anticipation of the emotional course of future experiences. This motivational pattern is not yet existent in the young infant, but it becomes noticeable early in the second quarter of the first year; from this time on it evolves to facilitate the child's

orientation to and interaction with his environment. It is rarely observed how much irritability of the parents toward each other, stimulated by inefficiency of the mother or by unavailability of the father's help, influences the development of the infant; even less investigated is how much the infant's thriving compensates for the emotional stress between the parents.

Is there any psychoanalytic evidence that would support the thesis that the child, being the object of the parent's drive, has, psychologically speaking, a similar function in the psychic structure of the parent? Does the child, evoking and maintaining reciprocal intrapsychic processes in the parent, become instrumental in the further developmental integration of the parent? Observations and psychoanalytic investigations yield positive and negative examples of the intrapsychic processes of the parent in reaction to the child.

Imitation is a well-studied aspect of the parent's interaction with the child. The imitating child holds up a mirror image to the parent. Thus the parent may recognize and even say to himself or to the child, "This is your father; this is me in you." If the child's imitative behavior shows the positive aspect of their relationship, the parent will like what he sees and consequently will feel that both child and parent are lovable. Imitation then reinforces the positive balance of identifications. It can also happen that the child shocks the parent by exposing the representation of hostile experience in the past or in the present. In this event the parent feels the child's rejection

and withdraws from him, even if just for a moment, since the unloved self equals the unloved, unlovable child. Imitation externalizes what has been internalized from infancy. It exposes not only the child's identification with the "omnipotent" parent but also his anger because of frustrations imposed upon him by the parent. The parent's responses to the hostile imitation of the child is a record of his acceptance of the growing independence of the child with whom he identifies in the process. It should not be forgotten that any manifestation of the child's positive identification with a parent reassures that parent: "I am a good father"; "I am a good mother."

Normally the child's idealization of the parent gives the parent gratification. There is no need to describe how fathers respond to the admiration of their sons or to the flirtation of their three- to four-year-old daughters. Just as obvious is the mother's pleasure in her daughter's wish to become like her or in her son's promise to marry her because she is the best, the most beautiful mother.

Much has been written about the oedipal child, but, except for the actually seductive, pathogenic behavior of parents, very little has been written about the parents' participation in the development of the normal oedipal phase. This may be explained by many parents' restrained physical contact with the child of that age, by the tendency to hide, to forget, actually to repress libidinal impulses that were more freely expressed with the

younger child. On the other side are those parents who, under cultural influences, assume that any sexual control is inhibiting to the child's psychosexual development. This mistaken rationalization allows them to expose their children to undue sexual stimulation, yet such parents often have to struggle with their own conflicts and with the psychological consequences of their laxity during later phases of their parenthood.

Psychoanalytic investigations have revealed that parents anticipate the child's failure in the area of their own developmental conflicts. Unconscious as the motivating conflict remains, the symptom is remembered. Well known to all of us is the parent who, because he or she was enuretic as a child, concentrates anxiously on the toilet training of the child. Even if this has been successfully achieved at an early age, such parents anticipate a relapse, especially when the child approaches the age at which their own relapse occurred. One may generalize that, unaware as parents usually are of the repressed conflicts of their childhood, the transactional processes evolve relatively smoothly until the child reaches the developmental level in which the parent becomes insecure in his response to the child's behavior. The anxious behavior of the parent is instrumental in conveying to the child the parent's own fixation.[2] The fear that a childhood symptom may be repeated by the child does not necessarily lead to anticipation that this will occur. Looking back at the childhood symptom from the security of his adulthood, the parent relives with the child his own conflict, now without fear. In the

successful interactions with the child, the parent resolves his own developmental conflict, with an addition to his self-esteem: "I am a good parent."

Each parent has to deal in his own way with the positive as well as the negative revelations of himself in the child. "It is the individually varying degree of confidence in oneself and in the child which enables the parent not to overemphasize the positive and not be overwhelmed by the negative aspects of the self as it is exposed through the child" (Benedek, 1970 p. 131). With the help of the positive manifestations of the child's development, the parents' confidence in their child grows and with it grows the conviction that they are achieving the goal of their existence. In terms of dynamic psychology this means that while the parents consciously try to help the child achieve his developmental goal, they cannot help dealing unconsciously with their own conflicts, and thus they achieve a new level of maturation themselves.

Parenthood during the Life Cycle[3]

Parenthood implies continual adaptation to physiological and psychological changes within the self, parallel to and in transaction with changes in the child and his expanding world. In discussing the limitless variations of conflicts recurring during the life cycle of the parents, it is helpful to conceptualize parenthood as a process that has an early, a middle,

and a late phase. With each child all parents live through these three phases, which necessarily overlap. Parents can be in the late phase of parenthood with their oldest child and at the same time be young parents with their youngest child.

Parenthood as an experience is more in focus during the early phase, which Kestenberg refers to as "total parenthood." The parent's involvement with and responsibility for the child is almost exclusive during infancy. The reciprocal psychodynamic interactions are most significant during infancy and the separation-individuation phase. But even in these early years there are exceptions to total parenthood. In many cultures mothers have helpers within the kinship; in our society the upper classes may have maids, nurses, or governesses who take over the duties of the mother; in other situations mothers go to work and therefore need helpers. Besides these, nursery school and kindergarten shorten the period of "total parenthood." But before school age the child's developmental needs for expansion are basically under parental surveillance.

The beginning of school in Western civilization coincides with the age and maturational level to which Freud attributed the end of the oedipal phase. With this the mental development achieves the ability to incorporate the expanding environment of classroom, teacher, and classmates. School, a socially regulated partial separation of parents from their children, facilitates

the repression of the Oedipus complex; this induces the latency period. Kestenberg states, *"Latency stands out as a time of part-time parenthood!"* (p. 305), meaning by this only the diminishing activities involved in childrearing. Yet it is worthwhile to mention that fortunately this separation evolves slowly, since otherwise it would activate fear or negativistic reactions in the parents against the growing independence of the child and against those who promote it. Usually the second and third child replenishes the libidinal supplies of the parents (more that of the mother than the father) when the first child reaches school age.

One could discuss the reciprocal developmental processes from the viewpoint of the parents' psychological separation from the child. Such conceptualization, however, does not cover parenthood during the life cycle. Conceptualizing parenthood according to its early, middle, and late phases affords the opportunity to organize the most frequent problems of parenthood as they change in time, keeping in focus the transactional processes between the generations.

Parents are total parents with each of their children and live through the early phase of parenthood with each of them until and through various stretches of their adolescence. The overlapping phases of parenthood, however, may cross the boundaries between generations. It is not infrequent that a young grandmother is at the same time a young mother. Paradoxes of

family lineage may thus occur. The baby of the grandmother is the aunt or uncle of the child born to a son or daughter.

In the early phase of parenthood the mutuality of the ongoing processes of identification-separation dominates the psychic economy of the parent-child relationship. The shift in these processes pushes the child in the direction of separation, the parents toward holding on.

During the preoedipal and oedipal phase the evolution of the dominant libidinal conflict and the corresponding ego growth activate unconsciously motivated, characteristic responses in the parents. Normally these responses quickly disappear under the pressure of the newly arising developmental trends in the child. Secure in their love for the child, parents rarely feel responsible for his passing problems. All that happens seems to be open to the empathic understanding of the parents; therefore, they respond with the feeling that it is natural, that the child will outgrow it.

School age often disturbs the security of the parents. School represents authority for the parents as it did when they were children. School means to parents that their child's behavior, his performance at work and at play will be exposed to scrutiny, and thus the parents themselves feel exposed. In order to diminish their disconcerting feeling of responsibility and also their (probably) hurt narcissism, parents eagerly supervise the various sources of

extrafamilial influences that their children experience. Their vigilance is often biased by prejudices and preconceived ideas. Playmates and neighbors are judged. Television programs are considered welcome entertainment; their influence upon the child—good or bad—usually cannot be assessed by the parents.

Yet parents observe with concern that their children are growing up faster than they did themselves. Very often they seem to want to slow down the tempo of externalization that characterizes the growth of the latency child. On the one hand, they would like to hang on to the past when they felt that they knew everything about the child; on the other hand, they have to weigh the child's competitive achievement with their ambition that he should perform on every level with adequate competence. But modem parents are wrought with apprehensions regarding educational aims.

While they conscientiously strive to bring up independent, secure, and efficient individuals, they refrain from applying controls lest the child become inhibited through punishment and grow up to hate them.

These conflicting problems of modern parents are pointed out here to illustrate the difference in the educational tasks of parents of preschool children and parents of latency children and adolescents. The preschool child evokes in the parents empathic, affective, goal-directed responses to behavior

that is a manifestation of a maturing individual. Whereas with young children the parents' developmental past refers prevalently to unconscious processes, in response to latency children and adolescents, parents remember their own behavior and its consequences. Conscientious parents' emotional responses to the problems set by their children of that age are motivated by reaction formation to the actual or psychological consequences of their own experience.

This model seems to apply mainly to those parents whose developmental past justifies their wish to provide their children with better conditions than they themselves had. However, there are many parents who, raised by permissive parents, grew up with the advantages of an affluent society. They, too, want to bring up their children to become productive, capable, contented adults. Can one formulate the educational task of such parents? It is beyond the scope of this chapter to discuss the transactional phenomena that set normative goals for the children of such parents by holding parental ambition within limits realistically measured by the capacity of the growing individual.

An essay on the psychobiology of parenthood should concentrate on parental reactions to the sexuality of their children. A half century ago one could have responded to such a request with a simple statement. The puritanical sexual mores invested in the Judeo-Christian tradition of Western

civilization deny the existence of sexuality in human beings until marriage. Now parents observe the sexuality of their children and usually deal with it according to the state of their own conflicts. They are not too disturbed to observe a young child playing with his genitals. The father who threatens a three-year-old child that he will "Cut it off" is becoming rare. During the boy's latency fathers usually are more concerned with the son's athletic ability and with his general manliness than with his sexual behavior. With the increasing sexual freedom among adolescents, fathers become concerned when their 16- to 18-year-old son is not sexually active. On the same basis they feel differently toward their daughter. As they suppress their own libidinal interest toward their daughters, they assume that girls are blissfully innocent. Mothers are different. Being more aware of their defensiveness against sexual impulses, they often become suspicious when children, even of the same sex, play together behind closed doors and are too quiet. Mothers are intent on protecting their children, the daughters more than the sons. Their worries become intensified when the period of dating begins and rarely cease until the daughter lands safely in marriage. Regarding their sons, their worries are different in degree, but not in kind.

In general, one may say that women who feel positively about their femininity and enjoy sexuality are usually less envious and less suspicious of their daughters' sexual lives. They trust their children since they trust themselves and their own experiences. In their intuitive confidence in the

power of their own personalities, they feel they have conveyed to the children their own value system and what is in accordance with it is anticipated without anxiety. However, such mothers are also shocked sometimes by disappointment. Self-confident parents have such an intrinsic need to trust their children, to assume that "what should not happen cannot happen," that they are often blind to the obvious. There are parents who want to be even more modern; they convince themselves that this is "her life," and that they want her to "live it fully." They are shocked by the realization that they have deceived themselves; the daughter's pregnancy becomes their personal shame; the disappointment in the daughter is their own failure. The middle-aged mother might respond with a serious depression to an event whose emotional significance she has denied. Even parents who trust their children and enjoy their confidence are left in the dark about the most important experiences of their children. This probably must be so. If it is sincere, sexuality is a private experience between two individuals; it is least communicable to parents.

Mothers whose behavior toward their children is characterized by intrusive vigilance have usually repressed their own sexuality and had neurotic conflicts. Women having little or no confidence in their femininity usually convey their insecurity to their children. When the period of dating comes, they realize that their daughters are not popular, their sons are not going out with girls. The insecure mother relives her own adolescence with

pangs of waiting, of being left out, of being alone. Such mothers suffer more than fathers from the inferiority feelings of their children. They begin to push their adolescent children; they advise and scheme in order to help. Painfully aware of the well-meant but unbearable concern, the adolescent tries to escape. For daughters as well as for sons, college or work away from home appears to be the best way to find relief. This often leads to emancipation of the daughter and the son; it permits new experiences away from the watchful eye at home.

Fathers are helpful by being more tolerant of the daughter's lack of popularity. The more usual complaint of daughters about their father is that he scrutinizes the boys too closely, criticizes them frankly, and often tries to scare them away. One can say that fathers have a double standard regarding their adolescent children's sexuality. They watch with Argus eyes over the virginity of their daughters, but unconsciously identify with their son's experience; they smile at the young girl with whom the son is in love as long as there are no consequences. For father, traditionally, propriety ends when the son comes home downhearted to announce that the girl is pregnant.

The variations of individual experiences of the *middle phase of parenthood* are many, but the main characteristic is the parent's involvement in and preoccupation with the children's sexual life. Whether this be traditional courtship under the watchful eyes of parents, or the now frequent

series of love affairs leading to consecutive promiscuity before marriage, it is all to culminate in marriage. Whether the parents' marriage is happy, just tolerable, or a cauldron of explosive emotions, no matter how deeply the marital struggles of the parents influence their children, all of the past is forgotten and the future appears rosy in the light of a new marriage. Except when difference in race, religion, and social status seems irreconcilable, both sets of parents unite in their hope that the children will live happily ever after.

With a child's marriage the immediate responsibility of parenthood for the child discontinues. The parents cease to be closest of kin by law, since the new husband and wife, even if they have known each other for only a short time, become next of kin. Parents feel this first probably when the wedding is over and they come home to rest. Then they begin to feel and rationalize about their sudden sadness. These parents may still be young people, living in the unity of early parenthood with their younger children, yet they have entered the late phase of parenthood with the newly married child.

In cultures in which the young wife customarily has to leave her parental home to live in the parental home of her husband, the marriage of the daughter represents an almost complete separation. The mother has neither the right nor the opportunity to remain involved with her daughter. In our civilization it is still not uncommon that both sets of parents of the young couple live close to each other, are neighbors or friends, that the young

people had known each other from childhood. Marriage in such a situation does not involve such sharp separation, does not require such a difficult adjustment. In our present culture, when neither social nor geographic boundaries restrict the choice of a mate, marriage often implies separation of parents from their children, which may activate a critical phase of parenthood.

In any case the marriage of a child represents a new adaptational task for the parents; they have to encompass the husband of the daughter or the wife of the son, not only in their own family, but also in their own psychic system as an object of their love. Psychologically this occurs through the identifications with their own child. The object relationship to the in-laws remains shaky for a time. The ambivalence easily flares up, rationalized by the parental concern for the happiness of their child. Just as when the child first went to school, parental narcissism makes them see the fault in the other rather than in their own child. Yet the young couple can "fight it out" and settle the differences more easily when the conflict remains their own problem and does not spread in circles like pebbles thrown in a pond. In this respect mothers are more often at fault than fathers.

Mothers often cannot relax their influence on their daughters; they identify with the married daughter or son and want to be involved in, or at least informed about, every detail of their life. Whether we see the problem

from the point of view of the young husband or the wife, the mother is almost always the "in-law," the often feared, critical investigator of one partner of the marriage. Yet today one sees very definite changes in this respect. As long as daughters grew up in families in which they owed devoted dependence to their mothers, even when married, they accepted the mother's opinion with unquestioning deference. Such "good" mothers were the "feared mothers-in-law," the butt of jokes, ridicule, and hidden or open hatred. Now the more self-reliant woman's husband does not need to fear that his wife has to side with her mother. Mother-in-law jokes have almost disappeared from magazines, indicating a significant change in the structure of the family and in the relationship between the generations.

The example of mothers who cannot psychically separate from their married children shows the more universal psychological problem of the late phase of parenthood. The slogan "generation gap" is not affixed to the adaptational problems of the late phase of parenthood, for obvious reasons. But there are some factors that seem to justify a comparison. One of the characteristics of the late phase of parenthood is the emotional consequence of the married children's alienation from their parents. Whether the parents are middle-aged or older, the child who becomes a parent does not have the same psychological relationship with the parent; his psychic structure has changed. More than the deepening relationship with the spouse, parenthood does change the psychic structure of the young parent. The parents of

married children have to adapt to their not being needed as they were before; this reduces the parents' self-esteem. This generation gap does not cause vehement upheaval, since it is not stirred by the maturation of adolescence, but by slow evolution of the late phase of parenthood. The gap between generations, which began with marriage and parenthood of the young generation, now deepens because of the physiological factors of aging. The psychophysiological reactions to "change of life" in women intensify the mother's emotional reactions and make her aware of all that which "hurts" in aging, even without severe, clinical depression. Yet her sensitivity increases the rift between the generations.

Fathers usually do not get into similar troubles of alienation at such a relatively early age as mothers. One reason for this is that fathers maintain more distance from the interpersonal problems of the family. As long as the father's ability to work is not diminished, aging has a mellowing effect on his attitude toward his children. In the disquieting experience of alienation from their married children, normal, healthy fathers frequently function as negotiators, trying to make peace and avoid a rift. The late phase of parenthood arrives later for fathers than for mothers, or it seems so because at that age level fathers become more interested and therefore more involved with their families than they were previously.

Before the last phase of actual "childless parenthood" arrives, late

parenthood brings about the gratification of the life cycle,*grandparenthood.*

Psychoanalysis of both men and women whose married children are childless, whether voluntarily or because of infertility, reveals disappointment and frustration, and also the source of the anxiety caused by this condition. Sometimes these individuals have guilt feelings and blame themselves for wishing for something beyond their ken. The somatic correlations of such depressive states originate in the wish to survive in the grandchildren.

There is a noticeable difference in the attitude of the prospective grandparents toward the pregnancy of the daughter. Fathers do not identify with the experience of pregnancy as do mothers. Prospective grandmothers remember what their mothers told them about the pleasurable or frightening experience of delivery and lactation. The prospective grandmother, reliving her own pregnancies in identification with her daughter, in her wish to protect her daughter, may convey her anxiety to the pregnant woman. Such anxious overidentification of the prospective grandmother, however, often interferes with the actual bliss of grandparenthood.

Grandparenthood is parenthood one step removed. It is a new lease on life since grandmothers as well as grandfathers relive the memories of the early phases of their own parenthood in observing the growth and

development of the grandchildren. Relieved from the immediate stress of motherhood and the responsibilities of fatherhood, grandparents appear to enjoy their grandchildren more than they enjoyed their own children. Since they do not have the responsibility for rearing the child toward an unknown goal, their love is not burdened by doubts and anxieties; they project the hope of the fulfillment of their narcissistic self-image to their grandchildren.

The indulgence of grandparents toward grandchildren has its psychodynamic (instinctual) motivation. If the relationship between the grandparents and the child's parents is not burdened by jealousy and hostility, open or suppressed, the grandparents can feel free to love their grandchildren. This does not mean just giving candy and toys or playing with them. The love of grandparents gives the child a sense of security, in being loved without always deserving it. What does the grandparent receive in return? A loving glance from a happy child, a trusting hand, an actual appeal for help; whatever it is, it is a message to the grandparent that he or she is needed, wanted, loved. Grandparents accept gratefully the reassurance from the child that they were, and still are, good parents.

Grandchildren, however, grow up and grow away from grandparents. As they reach adolescence, their attitude appears to reach that postambivalent phase of object relationship that Karl Abraham described as characteristic of maturity. The ambivalence of adolescence, the rebellion of youth are directed

toward the parents, who are the objects of their conflicting instinctual drives. The relationship with the grandparents is never so highly charged; therefore, the grandparents become the recipients of considerate and indulgent behavior by the maturing individuals, who, in the awareness of their strength, see the weakness of the doting grandparents even earlier than might be justified. The grandparents respond to the manifestations of the protective, somehow even condescending love of their grandchildren as balm for whatever wounds old age inflicts upon them.

Grandparenthood is, however, not the same for everyone. There are differences depending on the personalities of the interacting individuals belonging to three generations. The emotional content of grandparenthood and the expectations of the young parents in regard to them depend upon the cultural and socioeconomic changes in the family structure.

Of the many factors that influence the emotional meaning of grandparenthood, the chronological age of the grandparents is probably the most significant. Experience of grandparenthood has different emotional colorings if the grandparents are young, still in possession of their procreative capacities. It is obvious that the involvement of grandparents in such families overshadows their emotional need for grandchildren. This need seems urgent when the grandparents are well over their procreative period and they have had to wait a long time for grandchildren.

Old age, if not hastened by illness, arrives slowly, bringing with it the adaptive tasks of aging itself. From the multitude of these tasks, only those will be mentioned that influence intrafamilial relationships and consequently the status and function of the elderly parent in the family. In order to put this in a psychodynamic frame of reference, the overall psychodynamic character of each major phase of the life cycle is pointed out: (1) from infancy through adolescence the vector of metabolic and psychological processes is self-directed, i.e., receptive; (2) during the reproductive period the vector is expressed in the object- directed, expansive, giving attitude of parenthood; (3) as the supply of vital energies declines with aging, the positive, extraverted tendencies slowly become outweighed by the energy-conserving, restricting, self-directed tendencies of old age. These unconscious factors bring about the psychological (often psychiatric) manifestations (symptoms) of old age; they motivate also the psychological processes that bring about the age-determined changes between parents and their children.

The style of aging depends more on the personality pattern than on chronological age. Since aging reduces the libidinal expansiveness of the individual, the hostile components of the character become more pronounced. This explains the domineering, know-it-all behavior of many aging mothers and grandmothers, who become embittered if the younger generation does not follow suit as they did earlier. When the pattern and course of the psychodynamic processes of the parent are known, it is not

difficult to establish the distortions caused by the involutional processes of the parent and understand with sympathy the influence that old age exerts within the family.

There is no doubt about the specific blend of narcissism in the aged. Since it cannot draw upon fresh resources of libido, it enlarges the remaining resource by identification with the young and by rekindling the memories of past gratifications. Current frustrations increase preoccupation with memories of youthful experiences. Being engrossed in what one was often becomes irritating, even to the grandchildren, let alone to their parents. But this irritation means increased frustration and makes increasing demands in the senescent. The senescent person's ability for empathy with the younger generation diminishes. The defenses of the self-centered personality become more tenacious so that the younger generation's complaints about the egotism of the old are justified. The solace offered by the younger generation usually does not satisfy the senescent since he unconsciously wishes and, in some ways, consciously demands that his children and grandchildren remove the burdens of his age and make him unaware of his weakness. Many manifestations of "nonparenthood" with "nonchildren" can be described and explained; they all illustrate the complete turn of the cycle. As one time the parent was the need-fulfilling object of the child; now the "adult child" or the middle- aged child is the need-fulfilling object of the aged parent. The old parent, however, clings to the status of being a parent. Originating in the

instinct for survival in the offspring, parenthood establishes a sense of identity that integrates the biological and social functions of the personality.

Being a parent is at the center of a normal parent's self-concept. In old age, removed from his procreative period by two generations, he clings to his adult children and seeks in them the psychic images they once had been and therefore will always remain, his children. Supplied by memories of past experiences, parenthood is timeless. In the sense of intrapsychic processes, parenthood ends when memory is lost and psychic images fade out.

Chapter 24

Psychological Aspects of Divorce

Richard A. Gardner

Of the 2,146,000 marriages reported in the United States in 1969, one in three may reasonably be expected to end in divorce. This rather high proportion of failed marriages by no means represents a sudden collapse of the institution. According to Census Bureau figures, the divorce rate in the United States has been rising since the turn of the century. In 1890 the divorce rate was 5 per 1,000 total population. In 1946 the rate was 4.6—a peak that is explained by the wholesale dissolution of ill-considered "war marriages." After 1946 the divorce rate gradually decreased to a low of 2.1 in 1958. Since then the rate has been climbing steadily; figures for recent years are: 1966, 2.5; 1967, 2.6; and 1968, 2.9.

In 1969 there were 660,000 divorces—a figure that represents a rate of 3.3 per 1,000 total population. Since 2,146,000 marriages were reported during this year, the ratio of divorces to marriages is 660,000/2,146,000 or 1/3.25. This ratio is the basis for the prediction that one in three marriages

will end in divorce.

This figure cannot, however, be considered an accurate projection. Since the number of reported marriages is increasing every year, there is no direct correspondence between 1969 marriages and 1969 divorces. The latter represent a chronological accumulation of failed marriages that began over a wide range of previous years, any one of which had fewer total marriages than 1969. Therefore, the possibility of a 1969 marriage ending in divorce is probably greater than one in three.

The latest Census Bureau figures on the duration of marriages that ended in divorce are for the year 1967. The median duration was 7.1 years. The modal duration was between one and two years. Other generalizations regarding divorce may be drawn from the Census Bureau data. There is, for example, a greater risk of divorce for those who marry in their teens. The percentage of divorces involving children also appears to be increasing. In 1953, 45.5 percent of the divorces in the United States involved children; in 1958 the figure was 55.1 per cent; and in 1963 the percentage was 61.1. Apparently the belief that marriage should be maintained "for the sake of the children" is losing its force.

Within the United States there are significant regional variations in the divorce rate. In 1963 the rates were 0.9 per 1,000 total population in the

Northeast, 2.2 in the North-Central states, 2.8 in the South, and 3.6 in the West. These regional differences are in part related to varying degrees of permissiveness in state laws regarding divorce that encourage what the Census Bureau calls "migratory divorces." In 1967, for example, the divorce rate in New York was 0.4 per 1,000 total population while Nevada had a rate of 22.3. The divorce rate in Nevada was thus 56 times the rate in New York. Far from being a statement about the relative stability of marriages in the two states, the figure primarily expresses the fact that a great many New Yorkers were going to Nevada to obtain their divorces. In spite of migratory divorces, however, the West has had a higher rate of divorce than the East since the beginning of the century.

How do divorce rates in the United States compare with those of other countries? Although almost all countries report their annual divorce totals to the Statistical Office of the United Nations, which publishes them in the *Demographic Yearbook*, meaningful comparisons are difficult. A number of countries, including Argentina, Brazil, Chile, Colombia, Ireland, Malta, Paraguay, Peru, Philippines, and until 1970, Italy, do not provide legal means for the dissolution of marriage.

Table 24-1.
Number of Divorce Decrees per 1,000 Population Granted under Civil Law in 1968

United States	2.91

U.S.S.R.	2.73
Southern Rhodesia	2.14
Hungary	2.07
Egypt	1.92
South Africa	1.72
East Germany	1.68
Czechoslovakia	1.49
Libya	1.41
Sweden	1.39
Austria	1.32
Bulgaria	1.16
Finland	1.15
Yugoslavia	1.02

Source: *Demographic Yearbook*, United Nations, New York, 1969, pp. 671-674.

Although Table 24-1 lists the countries with the highest divorce rates

for 1968, the order is somewhat selective. For example, the Falkland Islands reported a divorce rate of 2.50, which would make it third highest in the world. The population of the islands is so small, however, that only five divorces were necessary to achieve this rate. Factors other than population must be considered in comparing divorce rates between nations. Figures reported for Southern Rhodesia and South Africa, for example, include only the white population.

Psychosocial Factors in Marriage That Contribute to Divorce

If one marriage in three is doomed to failure, it is only to be expected that some would advance the opinion that monogamy is not congenial to man's basic personality structure. The ever rising divorce rate has led others to consider monogamy outmoded or dysfunctional in our highly mobile and specialized technological society.

In opposition to the preceding theorists, Kardiner has argued persuasively that man has tried practically every conceivable arrangement for marriage and childrearing and monogamy has proved to be the most effective, its deficiencies notwithstanding. It allows for the closest continuous contact between parent and child that all agree is essential if the child is to become a self-sufficient and contributing member of society.

In discussing alternative systems, such as the polyandrous Marquesan

Islanders whom he studied intensively, Kardiner convinces the reader that the mother's incredibly complex interactions with her three to six husbands leave her but scant time for her children. Polygamous cultures, on the other hand, foster intense rivalries between the males that distract them from domestic involvements. A multiplicity of maternal or paternal figures confuses the child and lessens the likelihood of strong attachments.

Bettelheim confirms Kardiner's point in his recent study of children raised in Israeli kibbutzim. Although describing an encouragingly low incidence of juvenile delinquency, drug addiction, and severe emotional disturbance, he nevertheless concluded that the child raised in a setting with diffused parental figures tends to be more detached in his interpersonal relationships than children raised in more conventional settings.

Given the reasonably durable nature of the monogamous relationship, what is there in the Western variety, and that found in the United States in particular, that causes disequilibrium and divorce?

When two people marry today, "love" is taken to be the primary and only acceptable reason. While secondary considerations such as physical attractiveness, similar interests, status, and money may be admitted, anyone who states that he is marrying without "being in love" is branded with pejorative labels. He is "materialistic," "opportunistic," "sick," or "foolish." As

with other psychological phenomena in the human repertoire, cultural influences have played an important role in the formation, manifestation, importance, and meaning of love.

The romantic love that Westerners deem so necessary to marriage is a legacy of the early French Renaissance and the chivalric tradition. The ancients had sung the joys and struggles of love, but it was not until the thirteenth century that the concept of courtly love gained acceptance and began to dictate such requirements and proofs of passion as the abdication of all selfish motives, complete fealty, and Platonic idealization of the beloved. Without entirely excluding sensuality, the new love placed great emphasis on purity and virtue. As Huizinga says, "Love now became the field where all moral and cultural perfection flowered." Such a marital relationship was considered to be far superior to those arranged for mundane considerations by parents and overlords.

People marrying today are undoubtedly freer to explore the pagan possibilities of their bodies than their forefathers. Nevertheless, they still feel strongly that to get married there must be a spiritual bond, euphoric feelings, and at least a measurable degree of fidelity. Some part of these feelings must be attributed to novelty. Whatever the composite origin, they do not seem to endure in marriage with its inevitable restrictions, frustrations, and inescapable confrontations not only with the partner's all too human defects

but also with the simple realities of mundane cohabitation. In discussing these romantic expectations, Kubie condemns them for exacerbating the major neurotic elements in marriage that are "inflated and reinforced by the romantic Western tradition which rationalizes and beatifies a neurotic state of obsessional infatuation. ... It is an obsessional state which, like all obsessions, is in part driven by unconscious anger." The disenchantment that accompanies the waning of romantic euphoria is frequently associated with divorce. "We are no longer in love" is probably the most common reason given for divorce.

An adjunct of the chivalric inheritance is the notion propagated in our culture that marriage will increase one's personal happiness. In the extreme, as Ackerman describes it, "marriage is approached as a potential cure for whatever psychic ails a man may suffer." The failure of marriage to supply this elusive happiness plays an important role in divorce. This quest is a factor driving some from one marriage to another. Hunt believes that "the wide use of divorce today is not a sign of a diminished desire to be married, but of an increased desire to be happily married."

Our Western society places a premium on youth and beauty. Many men display their wives in accordance with Veblen's principle of conspicuous consumption. A marriage based *primarily* on such attraction cannot but falter with the inevitable changes brought about by the years.

In American society an ideal, "happy" marriage is considered to be one in which there is an interlocking of needs and mutual gratifications in the higher areas of functioning. "Togetherness" is extolled to such a degree that those who wish to look elsewhere for some of their important satisfactions (not necessarily sexual) may consider their marriage defective. In no other relationship are such demands made. The "togetherness" a couple feels in college, for example, where interests are not only shared but also similar, may begin to evaporate when the husband begins to acquire the highly specialized skills necessary for success in our technological society. He can no longer communicate his major interests to his wife, and this breakdown in "togetherness" may contribute to the decision to divorce.

There can be little doubt that increased social mobility has contributed to a greater incidence of marriages between persons of different class and value systems. Montagu considers such marriages to be intrinsically unstable because they lack the stabilizing influence of a shared kinship group.

Perhaps reflecting the social relaxation of restrictions and prohibitions, religious strictures against divorce have been eased, and religious obligations and commitments no longer impede the dissolution of an unsatisfactory marriage.

While increased social equality for women has given them more power

to extract themselves from a painful marriage, it has at the same time engendered professional interests that may conflict with their childbearing and homemaking desires and obligations. Some women dissolve their marriages in order to freely and unequivocally pursue their professional interests. Others remain married, but they are so guilt-ridden over role conflicts that their gratifications are markedly reduced.

Kubie suggests that one explanation for the increasing divorce rate may be the increasing life span. Marriages have always been fraught with difficulty, but the participants died before their years of agony could culminate in divorce. With an increase in divorce in the middle and late years of life, younger people have now had more exposure to the divorce experience. They are, Kubie feels, more likely to emulate their predecessors and feel more free to divorce.

Last, but certainly not least important, are the individual neurotic factors that contribute to marital discord and disillusionment. Kubie considers the neurotic difficulties to arise primarily from the discrepancy between the partners' conscious and unconscious desires in the relationship. Examples are legion. One woman unconsciously wants a father in her husband, and her spouse unconsciously wants a mother, although each vociferously professes the desire for an egalitarian relationship. Frustration mounts as their underlying demands are not met. Another woman may

basically relate best to a man who is dependent on her. All may go well in the early years of marriage when he relies on her efforts while he builds his career. Once he has established himself, there is no longer any realistic need for dependency, and the woman's neurotic necessity to perpetuate his anaclisis may cause divorce.

Ackerman emphasizes the factor of anxiety assuagement as a reason for getting married. The impotent man may marry a frigid woman to hide his deficiency. If either partner becomes more desirous of sexual activity, the neurotic equilibrium is disrupted, and marital discord becomes manifest.

Unfortunately divorce is rarely a solution to the damage and frustration caused by neurotic interaction in marriage. As Bergler says, "Since the neurotic is unconsciously always on the lookout for his complementary type, the chances of finding happiness in the next marriage are exactly zero. . . . The second, third, and nth marriages are but repetitions of the previous experience." Monahan concluded that second marriages are twice as likely to break up as first marriages, and that those who marry a third time are accepting an even greater risk. Specifically, if both spouses have been divorced two times or more, the probability of another failure is nearly five times greater than that for a first marriage.

The dire statistical projections of Bergler and Monahan are not open to

dispute. Bernard, however, presents a more optimistic outlook by suggesting that most first marriages lead to divorce not so much from neurotic factors but because of normal maladjustments and inexperience. "The experience of an unhappy first marriage, although it may constitute a high tuition fee, may nevertheless serve as a valuable educational prerequisite to a successful second marriage." Bernard does concur, however, with the finding that second marriages are 50 percent more likely to fail than first marriages. In Goode's study of remarried mothers 87 percent described their second marriages as much better than their first. Such statements cannot, however, be taken as satisfactory evidence of better second marriages. Having failed in one marriage, these mothers are less likely to admit failure in a second—even to themselves.

Despite encouraging signs, it appears that the same neurotic needs that drive a person into his first unfortunate marital relationship remain to influence his future attempts. As a psychiatrist I would like to believe that treatment can lessen the likelihood of divorce in subsequent marriages, but I have not been able to find any studies that satisfactorily confirm or deny the efficacy of therapy in this regard.

Consulting with Patients Contemplating Divorce

Since omniscience is a prerequisite for predicting whether a particular

patient will be better off married or divorced, it behooves the therapist to maintain a strictly neutral position regarding the question.

Generally, when the question of divorce arises, the therapist's efforts should be directed toward clarifying the issues and alleviating pathological behavior so that the patient may make healthier and more prudent choices. In all events the decision to divorce must be the patient's. He must feel that he took the risk on his own, that no one but himself is to blame if his decision turns out to be an unfortunate one, and that there is no one else to thank if his choice proves to be a judicious one.

The experienced therapist who speaks proudly of never having had a divorce in his practice is probably pressuring some of his patients into remaining married when both partners would be better off divorced. The therapist with a high frequency of divorces should consider the possibility that he may be inappropriately encouraging divorce when a more conscientious effort at working through the difficulties might have been preferable. When a therapist applies such inadvisable pressures, his own marital history often plays a role. If his own divorce resulted in a significant improvement in his life, he may tend to overstress the values of separation. If his own marriage is gratifying, he may strongly encourage working through when separation might be the more therapeutic course. And the therapist who has never been married, whatever his assets, is compromised in his

ability to appreciate fully the problems and conflicts of marriage.

Therapeutic consultations regarding divorce fall into three major categories: (1) those in which a couple enters therapy with the express purpose of averting an impending divorce; (2) those in which a patient already in therapy finds himself facing a decision regarding divorce; and (3) those in which one partner only presents himself in order to forestall or work through the problems of an impending divorce.

I agree with Whitaker and Miller that the ideal counseling situation is one in which the marital partners are seen conjointly by a therapist who has had no previous therapeutic experience with either partner. These circumstances facilitate the impartiality that is vital to such counseling. Not only does conjoint therapy allow the therapist to hear both sides of the story; it also permits him to observe the interaction between the couple. Further, if the outcome of the consultations is maintenance of the marriage, then the partners have had an experience in mutual inquiry that should serve them in good stead in their future relationship. If they decide to divorce, their sessions should leave them clearer about their reasons for separation. What they have learned may even help each avoid another unsatisfactory marriage.

In working with such couples the therapist must side only with health, supporting healthy and appropriate positions and discouraging pathological

and inappropriate behavior, regardless of who professes it. If he acts as a benevolent participant observer, there is less likelihood that either spouse will accuse him of favoring the other even though in any given session one may get more criticism than the other.

The therapist must resist either partner's attempts to use him as a tool in neurotic manipulations. The husband, for example, may try to enlist the therapist's support in influencing his wife to stay with the marriage when she is strongly inclined to terminate it. The wife may attempt to get the therapist to pressure her husband into drinking less or spending more time at home when he has little real motivation to do so.

Even if the therapist maintains the most careful neutrality, motives will be imputed to the therapist that are really the projections of his patients. The wife, for example, may believe that the decision to divorce was encouraged by the therapist because she needs support and agreement for such an independent step. The husband may consider the therapist's failure to condemn his infidelity as sanction.

When a couple seeks consultation to avert divorce, they often claim that they want to stay together "for the sake of the children," an attitude that has both realistic and pathological elements. Studies suggest that *on the whole* there is less psychiatric disturbance in children from broken homes than in

those from intact but unhappy homes. Nevertheless, one still cannot predict which will be the better situation for any given child. The realistic argument, therefore, that the spouses should remain together for the children is suspect; and I generally make it clear that one cannot know in advance whether or not the children will be better off.

Professions of concern for the children are often only rationalizations to buttress neurotic interactions. Sadomasochistic, overprotective, overdependent, symbiotic, or other pathological relationships may be serving as the basis of the marriage. The therapist should, insofar as it is possible, clarify these underlying issues for the couple while playing down the falsely benevolent considerations regarding the children's welfare.

Whitaker and Miller further recommend including the couple's parents and children in the consultations. I have done this occasionally and found it helpful. Information is often obtained that would not otherwise become available. Certain issues, however, are more justifiably discussed in the more intimate interviews with the couple alone.

Individual therapy with married patients presents special problems when the possibility of divorce arises. If therapeutic work with a married patient is successful, his healthier adaptations may be most anxiety-provoking to his spouse. The latter may become frustrated attempting to

maintain the pathological patterns of interaction. Sometimes the partner can form healthier patterns of relating, and the marriage may be continued along new lines. Often he cannot make these adjustments, and his only alternative is then to seek others who can provide him with the pathological gratifications that he craves. Therapy in such cases is, of course, instrumental in bringing about the divorce.

Even without healthier adaptations on the part of the patient in therapy, the intimacy that the therapist shares with the patient cannot help causing some feelings of alienation in the partner, and a marital schism may be widened as a result. In extreme cases the therapeutic relationship may precipitate divorce in a marriage that might otherwise have been realistically reconcilable.

The individual who presents himself for treatment because his spouse threatens divorce is a poor candidate for therapy. His motivation does not generally stem from an inner desire to change things within himself because of the personal pain his problems cause him. He comes, rather, with the hope of altering those aspects of his behavior that are alienating his spouse or with the intention of learning ways to manipulate his partner into staying.

Sometimes both partners are in therapy and one or both may refuse conjoint sessions because they would be in "foreign territory" with their

spouse's therapist. In such situations the couple is deprived of the benefits to be derived from the adjunctive joint sessions.

On occasion a patient may need the therapist's meaningful involvement to make the divorce process more bearable. This need may, in fact, be a primary reason for entering therapy when separation impends, and it is particularly applicable to women who, in my experience, are more likely than men to institute divorce proceedings without being significantly involved with a third person. Sometimes a spouse who feels guilty about instituting the divorce may encourage treatment for the partner who is left behind in order to assuage his guilt over the "abandonment." The same guilt-alleviating mechanism may be operative in the departing partner's encouraging (either consciously or unconsciously) the remaining spouse to take a lover.

Therapeutic Implications of Divorce Litigation

In the United States most states adhere to the adversary system in divorce litigation. Divorce laws, therefore, are predicated upon concepts of guilt and innocence, punishment and restitution. The divorce is granted only when the complainant or petitioner has proven that he has been wronged or injured by the defendant or respondent. Acceptable grounds for divorce are narrowly defined and, depending on the state, include mental cruelty, adultery, abandonment, habitual drunkenness, and nonsupport. The law

punishes the offending party by granting the divorce to the successful complainant. If the court finds both husband and wife guilty of marital wrongs, a divorce is usually denied. In actual practice, however, the attorneys negotiate a settlement that includes alimony, child support obligations, custody, and visitation privileges. Only a small percentage of divorce proceedings culminate in a contested trial.

Since the adversary system is antithetical in spirit to the mutually cooperative inquiry vital to successful joint therapy, such consultations are rarely successful once litigation has been instigated. The lawyer advises his client to withhold information that might endanger his legal position and to gather whatever data he can that might strengthen his case. Patients who are naive enough to think that anything therapeutically meaningful can be accomplished in such an atmosphere should not, in my opinion, be supported in this delusion by the therapist. I only accept couples for conjoint therapy on the condition that therapy will continue only as long as neither partner instigates legal action.

When a spouse instigates legal proceedings, the intent may not always be clear and the motivation is often fragile. For these reasons the lawyer's usual practice of recommending reconciliation at his initial meeting with his prospective client may have untoward results. It may have taken the prospective client many years to take a healthy step toward divorce, and the

lawyer's implied moral condemnation may serve to perpetuate a pathological situation. Others want to be told by an authoritative figure to work out their marital problems, and the lawyer's advice may help them proceed. Quite frequently the initial legal consultation is used by the spouse as a warning that the marriage has seriously deteriorated, and more constructive efforts on the part of both partners may result.

Once divorce litigation has begun, the woman, more usually, may try to involve the lawyer for other than legal reasons. This involvement, which doesn't necessarily include sex, may help the woman compensate for the loneliness and loss of self-esteem caused by the divorce. More pathologically she may be seeking a substitute neurotic tie to replace the one that is being severed. While every divorce lawyer has experience with these involvements, not all are aware of their psychological implications.

The therapist who must assume the role of King Solomon and offer recommendations about the custody of children is fortunate indeed when he meets parents who are genuinely seeking a solution that is best for the children. In practice, however, each parent usually pleads only his own cause, backed up by a lawyer who wants the psychiatrist's testimony only if it supports his client's case.

All too often custody discussions are distorted by exaggerated

emotional claims by each parent—the child and his welfare are subordinated to the desire to wreak vengeance on the spouse by depriving him of a prized possession. Under such circumstances psychiatric evaluation is most difficult.

It is preferable, therefore, that custody consultations be conducted by one who has not been, and will not be, the therapist for any of the children involved. His decision cannot fail to alienate the parent who has "lost" the child in litigation, which, in turn, jeopardizes future therapy with the child. Any child's chances of being helped in therapy are markedly reduced if either of the parents is significantly hostile toward the therapist. The child senses his parent's antagonism toward his therapist (even when not overtly expressed) and is torn between the two—hardly a situation conducive to a good therapist-patient relationship. Divorced parents can have a good relationship with their child's therapist, but it is hardly possible if he has participated in the custody decision.

The Divorce Decision

Generally the decision to divorce takes months and years to mature, no matter how explosive the announcement itself may appear. The prospect of what divorce entails may be quite frightening, and it may safely be said that the divorce decision, tainted as it is by so many negative aspects, is much harder to arrive at than the original decision to marry. Inertia and the

specters of loneliness and hardship plague both partners. Some may need a lover to help them bridge the gap. Ambivalent separations and reconciliations may be necessary, and the therapist must respect his patient's reactions, his need for desensitization and accommodation. Time itself can be very therapeutic, and it behooves the therapist not to pressure his patient into proceeding rapidly— even after the decision has been made and the divorce promises to be salutary.

Primarily because guilt is so pervasive at this point, the therapist is often asked "how to tell the children." I generally suggest that both parents together tell the children, describing the main issues in terms that are comprehensible to the child: "Mommy and Daddy don't love one another any more." "Daddy has had trouble drinking too much whiskey, and now Mommy is tired of his drinking and doesn't want to live with him any more." Withholding information is deleterious because it promotes an atmosphere of secrecy and dishonesty that the child senses and reacts to at a time when he most needs a trusting relationship with his parents.

Specific details such as impotency, frigidity, and more extreme sexual problems need not be disclosed. The child may request information on such matters, and he may be told that just as he has certain matters that are private, so do his parents. The important thing is to encourage the parents to establish an atmosphere of open inquiry in which the child has the feeling

that most of his questions will be answered. The child should, in fact, be encouraged to repeat his questions, for they are part of a process that is vital to his working through of the divorce.

Some parents hesitate to engage in open confrontations because they may get upset—a prospect they see as damaging to their children. On the contrary, such displays of emotion may be most salutary for they show the child acceptable ways to handle his own reactions. If parents aren't free enough to honestly express their emotional reactions, they can hardly expect their children to do so.

The Child's Psychological Reactions to Divorce

Since the divorce rate is highest in the first few years of marriage, the affected children tend to be young and, therefore, more vulnerable than older children to its deleterious effects. Bowlby's extensive review of the literature demonstrates that parental deprivation (especially maternal) is particularly conducive to the development of psychopathology and that the younger the child at the time of the abandonment the more severe the psychiatric disorder. Symptoms indicative of deprivation in the infant include loss of appetite, depression, lack of responsivity, and in the extreme, marasmus and death. In the older child, the reactions run the gamut of psychiatric disorders. It may be difficult to separate the effects of the divorce from those of the

traumas and prolonged strains that have preceded it. The divorce can even be salutary for the child because it ends the years of bickering and misery that have contributed to his psychological disturbance.

When the child first learns about the divorce, he may respond with denial. Some children will react so calmly to the announcement of their parent's forthcoming departure that the parent may seriously question his child's affection and involvement. Even after the parent has left, and the child has been repeatedly and painstakingly told about the separation, he may quietly ask when the parent will return or why he hasn't yet come back. Or the child may intellectually accept the fact of the divorce but go through his daily routines as if there were absolutely no change in his household. Such a child is repressing the inevitable emotional reactions that are evoked by the divorce, and his repression may be consciously or unconsciously sanctioned by the parents. Stoic advice such as "Be brave" and "Big boys and girls don't cry" may bolster the child's repression of his emotional reactions. The parents' decision not to express their own feelings in front of the children is another way in which the denial and repression reactions can be fostered.

Encouraging the child to express his grief is a far healthier reaction. It allows a piecemeal desensitization to the trauma. Play is an excellent medium through which some children can work through their grief reactions—in or out of the therapeutic situation.

Children may also react to the divorce with symptoms of depression, withdrawal, apathy, insomnia, and anorexia. About one-third of the children of divorce studied by McDermott were depressed and many exhibited accident prone behavior, unconcern with their safety, and suicidal fantasies. The depression is not simply reactive in many cases. Hostility redirected from the parents to the child himself and the feelings of self-loathing that the child feels because of what he considers to be an abandonment may contribute to the depression. The depression generally lasts about six to eight weeks.

Some children regress in an attempt to get more attention in compensation for that which has been lost. Overprotective parents and those who attempt to assuage the guilt they feel over the divorce by indulging the child may foster this adaptation.

Occasionally a child will run away from home—usually in an attempt to rejoin the departed parent. The enhanced attention that the act generates may also be a motivating factor. In addition, the hostile impulses that the child harbors toward the parents for the divorce can be gratified by his awareness of the worry and frustration that his absence causes them.

In working with such children it is important to help them accept their angry feelings so as to lessen the likelihood that it will be discharged through neurotic channels. It is also necessary to help them express their anger in

constructive ways—ways that will help rectify the situations that are generating it.

Acting out the anger in an antisocial fashion is common. The divorce may leave the child weak and vulnerable, and he may gain compensatory power through his violent actions. Observing his parents to be so flagrantly hostile to one another and so insensitive to each other's feelings may contribute to the superego deficiency that permits guiltless acting out. It is not surprising then that a number of studies reveal a relationship between juvenile delinquency and divorce.

The child may feel guilty and consider the divorce to have been his fault. He may believe that the departing parent can no longer stand his "badness" or that he has been too much of a financial burden. Often comments that the parents may have made during their altercations may be taken by the child as verifications of these ideas. Such guilt is complex. It may be related to oedipal problems. The boy may feel that his father's departure was caused by his own conscious or unconscious wishes. Girls may experience similar guilt when it is the mother who leaves. The guilt reaction is often related to the child's desire to gain control over this chaotic event in his life. Control is implied in the notion, "It's my fault." The child may reason: "If they got divorced because I was bad, maybe they'll get married again if I'm good." The hostility the child feels toward the parents for having divorced may also contribute to his guilt

feelings. Whatever the psychodynamics, to reassure the child that the divorce was not his fault is misguided; the fundamental issues that have brought about the guilt must be dealt with if it is to be alleviated.

On rare occasion the child may have contributed to the divorce. He may have been unwanted or he may suffer from a severe illness and the departing parent is unwilling to assume the burdens of his upbringing. Such children must be helped to appreciate that the real defect lies less within them and more with the parent who has left.

Anger is an inevitable reaction and it may be handled by a variety of mechanisms. Denial of it is common. The child has already lost one parent; he fears doing anything that might alienate the other. Some direct their anger toward the parent with whom they live, since the absent parent is not so readily available. Often the person who first instigated the divorce becomes the primary target—no matter how justified the initiation of divorce proceedings may have been. Other children have temper tantrums. Some may utilize compulsive rituals for the symbolic discharge of hostility; others project their anger and then see themselves as innocently suffering at the hands of malevolent figures. Nightmares are a common manifestation of the repressed hostility. Some handle their anger through reaction formation: they become excessively concerned for the welfare of one or both parents and fear that they will be sick, injured, or killed. Some harbor the notion that their

angry thoughts may harm the parent, and this produces guilt and fear.

Parental duplicity, often well-intentioned, may complicate the child's life. He may become confused over contradictions between what his parents say about their affection for him and how they act toward him. Father, he is told, still loves him although he never visits or sends support money. Mother is said to love him, yet she spends many nights and weekends away with strange men. His parents may adhere to the dictum that they should not speak unfavorably of one another to the child —lest his respect for the criticized parent be compromised. Here again confusion is engendered: the child can only ask, "If he was so perfect, why did you divorce him?" Such parental dishonesty (no matter how well-intentioned) can only create in the child distrust of his parents and confusion about what love is.

The child must be helped to perceive his parents as accurately as possible—as people with both assets and liabilities. This will lessen the likelihood that he will have unrealistic goals in his own marriage, and it will increase his chances of more realistic expectations from all people whom he encounters. In addition, he must be helped to appreciate that if there are deficiencies in the affection of one or both parents for him, this does not mean that he is unlovable. It means only that there is something wrong with a parent who cannot love his own child; and there is no reason why the child cannot obtain the love of others both in the present and future.

Many factors may contribute to the feelings of inadequacy that children of divorce almost invariably suffer. The child may consider the "abandonment" as proof that he is unworthy. He may feel that the parent with whom he has been left is as equally worthy of rejection as himself, further deepening his insecurity. The divorce produces a basic feeling of the instability of human relationships. If one parent can leave him, what is to stop the second from doing so as well? If his mother and father (whom he once considered to be omnipotent) cannot solve their problems, the world must be a shaky place indeed. If his mother, for example, can get rid of his father so easily, what is to stop her from getting rid of him with equal impunity? The parent with whom the child lives may attempt to make the child a confidant or force him to participate in decisions that he is ill-equipped to make. Although some children rise to the occasion and assume a maturity beyond their years, most become even more insecure as they observe themselves incapable of meeting the demands made upon them—demands that they may feel they should be capable of meeting. The parent with whom the child lives may become increasingly resentful of the child because of the greater responsibilities and restrictions placed upon him. This parent, in addition, may displace hostility toward the absent ex-spouse onto the child. Being the object of such hostility increases the child's feelings of worthlessness.

Some children develop severe separation anxieties. As mentioned above, having lost one parent they fear the other will leave as well. When the

separation anxiety becomes severe (such as when a school phobia develops), other factors such as unconscious hostility and death wishes are usually operating. The child needs to be constantly by the side of his parent to be reassured that his death wishes have not been realized. Such anxieties over hostility may contribute to the formation of other phobic symptoms such as exaggerated fear of dogs, injections, or heights.

After death the absent parent is usually idealized; after divorce there may be an opposite tendency to devalue the parent who is no longer in the household. In either case exaggerations distort the child's view of his parent, and healthy identification is thereby impaired. The child of divorced parents has fewer opportunities to use reality testing to correct the misconceptions he may have about his absent parent. He may devalue the parent who has gone in order to protect himself from the painful feelings of having been abandoned. It is as if he were saying to himself: "No great loss. He wasn't such a good person anyway." Although he may derive some specious solace from this defense mechanism, its utilization deprives him of a model for emulation, identification, and superego formation. Excessive idealization is also common. Often it serves as reaction formation to the feelings of hate and detestation the child has toward the parent who has left. To admit these feelings might expose the child to guilt and self-loathing. Such idealization also hinders the formation of valid identifications.
